Pathology with reference to the bile retention syndrome

J. L. EMERY

Department of Pathology, Sheffield Children’s Hospital

Summary
The pathological significance of giant cells, inspissated bile plugs and hepatic fibrosis in the liver of infants is critically reviewed. Evidence is presented suggesting that a wide variety of pathological change in the paediatric liver results from the interaction of the effects of growth, metabolic maturity, genetic metabolic variability and infection. Understanding of the bile retention syndromes might increase if the diagnosis of ‘Neonatal Hepatitis’ and ‘biliary atresia’ as finite conditions, were to cease and their pathogenesis considered in such a multifactorial way.

The study of hepatic pathology in young children has now reached a new stage. We are leaving the somewhat static concept of a series of isolated diseases of the liver and reaching one in which increased knowledge of the chemical activities of liver cells, an insight into the mechanisms of some virus affections of the liver, and more dynamic approach to the effect of disease processes on a developing, as distinct from a static, organ is forcing us now to think of liver disease in at least a type of four-dimensional way. The dimensions are: (1) growth; (2) metabolic maturity; (3) genetic metabolic variability; and (4) infection.

One of the present problems in discussing liver pathology in the infant is the difficulty in the use of terms as those in common use are usually related to unifactorial concepts of disease, and in particular, the use of the term ‘hepatitis’ in somewhat the same way as nephritis as applied to kidney disease, is ceasing to be meaningful. The well-established bacterial and allied infections affecting the liver such as syphilis, tuberculosis, Listeriosis (Hood, 1957), Entamoeba histolitica (Shute, 1947), and parasitic infections, and umbilical sepsis (Morrison, 1944), are well described and known not to require further discussion at this meeting but they can be correctly described as syphilitic hepatitis and amoebic hepatitis, and so on.

When we come to diseases of the liver related to virus invasion of the body, things are not so simple. The situation, again, varies in some degree with the particular virus (Pugh, Newns and Dudgeon, 1953; Stern and Williams, 1966; Strauss and Bernstein, 1968). The problem here appears to be that most of the viruses which affect the liver appear to be able to reside within the hepatocytes for varying periods of time in a state of apparent symbiosis and it is only when this symbiotic balance is disturbed that massive destruction of hepatocytes and the resultant calling into play of the usual inflammatory responses produces a situation which can legitimately be called hepatitis. Much current interest lies in the mechanisms that make a liver, existing in a state of virus symbiosis, go into a state of virus hepatitis. It is in this field that our immunological colleagues are, at the present time, having a field day.

Progressive liver destruction and failure also occur in association with metabolic diseases. Here the diseases which are of greatest current interest are those associated with Wilson’s disease, cystic fibrosis, and with alpha-1-antitrypsin deficiency. These conditions are important because we have some external guides by which we can measure them—the changes in the pancreas in cystic fibrosis, and the serological test in alpha-1-antitrypsin. Here we have diagnosable conditions that are sometimes associated with a progressive degenerative and inflammatory state within the liver, but more frequently are not. Others will discuss alpha-1-antitrypsin. Since cystic fibrosis and cytomegalovirus infections have long been amenable to the simple tools of my own craft, my observations on ‘neonatal hepatitis’ and ‘congenital biliary atresia’ have largely been derived from them.

The histopathology of the infant’s liver is made up of a combination of factors—multinucleate giant cells, infiltration with leucocytes, bile infarcts, fibrosis, retention products in hepatic cells, proliferation of bile ducts, the presence of inspissated bile plugs, vascular changes and bile-laden cells in lymphatics. Some of these that have gained perhaps undue prominence in isolation need brief comment.

‘Giant cell hepatitis’

‘Giant cell hepatitis’ is known to be a condition of the very young child and the discussion went on for years on the possibility that the giant cells are a specific reaction to a virus infection in the young
liver. I well remember taking part in a symposium in the Ciba Foundation 15 years ago that was chaired by the late Sir Roy Cameron in which we spent the whole day on this subject; some maintained that the presence of giant cells meant hepatitis of almost certain virus aetiology and others that such lesions could be produced as a result of congenital atresia of the bile duct. The answer is still not certain but most now consider that they are non-specific. I believe that the numbers seen are the result of a balance between the growth activity of the liver and the effect of living or non-living mechanisms altering the metabolism of the cell at the same time.

The giant cell state in the liver is progressively more prominent as the neonate is approached and even more so when one deals with intrauterine disease. The facts concerning the multinucleate cells were largely worked out by Popper and Schaffner (1963) and Oledzka-Slotwinska and Desmet (1969) who showed that there are no cell wall remnants in giant cells and that the chief characteristics of the cells are that the nuclei are smaller than normal hepatocyte cells and that they often show budding with rupture of the nuclear envelope.

The cytoplasmic activity of the giant cells varies very considerably. Some appear to be able to handle glycogen normally, others not. Cells also show varying abilities to handle iron and bile and there rests a nice problem as to why, in some of these livers, multinucleate cells are filled with iron or glycogen or fat and others, often cells adjacent, have a different chemical storage pattern (Reubner and Miyai, 1963). These giant cells can be produced by a number of factors and not necessarily be of virus aetiology. Campbell and Gilbert (1967) produced them using an E. coli endotoxin. It must not be forgotten that dividing cells are very common features of the normal liver in the very young child.

It is usually believed and, I think, true that most of these multinucleate cells will eventually degenerate and are destroyed—they are the result of incomplete cell division. Thus they are, at the same time, regenerative and degenerative. The situation is that of a boat tacking an estuary in a good wind, moving well over the water, but the movement of the tide makes the true movements, that over the bottom of the sea, something quite different from the appearances on the surface. The younger the child, the faster runs the tide!

**Inspissated bile plugs**

Small bile plugs can be found in the livers of a very high proportion of children dying within a month of birth if the child has been ill for more than a few days with almost any condition. This particularly applies to children who have surgical conditions of the gut with peritonitis. The bile plugs appear to be concentrated bile but they also contain protein and sometimes a little iron-staining material.

These bile plugs are not necessarily due to the complete blockage of the bile ducts because if one injects the common bile duct with a thin fluid such as Indian ink, it is possible to get the Indian ink up through the bile ducts and into the intercellular canaliculi beside the bile plug. This is by no means an easy manoeuvre and if a simple injection of the common bile duct is attempted, failure certainly follows. It is only possible to get the ink to penetrate if it is injected at a fairly low and constant pressure and the liver is gently palpated, squeezed and massaged for several minutes during this time. Fluid appears to have to be coaxed rather than forced along bile passages.

The bile plugs are associated with diminution and absence of the micro-villi of the canaliculi of the liver cells. It is easy to conceive of a situation in which once a bile plug has formed, a diminished fluid excretion could take place so that a vicious circle can be set up with a persistence of the plug. This is a situation that appears to occur in a number of instances, quite independent of those associated with general liver disease when an isolated plug occurs surrounded by a small rosette of abnormal hepatocytes.

The aetiology of inspissated bile plugs will only be certain when we understand the mechanism by which bile moves through the canaliculi and through the terminal bile passages. I have always been impressed by the continual movement of the form and shape of the liver consequent upon the movement of the diaphragm and it is my belief that there is an increase in the number of these inspissated plugs in conditions in which there is a defect in mobility of the diaphragm, whether it be due to an abnormal structure of the diaphragm, to the presence of peritonitis or of pleurisy. Thus it is my belief that a major factor in the movement of bile along the canaliculi is due to the continual movement of the liver. This lends support to the concept which was suggested by workers in Boston (Hsia et al., 1958), that massage of the liver may be of some assistance in bile excretion although I feel that enforced active respiratory movements may be the most effective chologogue.

Inspissated bile plugs also occur within the small extra-canicular bile ducts as, indeed, the cells of these ducts often show the presence of bile granules in their cytoplasm and appear to show similar reactions to the formal hepatocytes. These occur similarly in livers where rubella is involved as well as those in which no known infective agent is recognized.

**Fibrosis**

One of the characteristics of infant tissue is that
the amount of connective tissue is prominent. This is perhaps well seen in the pancreas and, since the pancreatic ducts and bile ducts are almost brothers, it is natural enough that the structure of the portal triads has a parallel development. The connective tissue in the young liver is more labile than in adults and care must be taken not to overemphasize the importance of ‘fibrosis’ of the liver as the amount of fibrous tissue in infant livers does not necessarily imply the same severity of disease and prognosis of that in adults.

In taking needle biopsies from livers in children it is wise deliberately to sample either the right or the left physiological lobe as, in the ill newborn, the left frequently shows a much increased amount of connective tissue and this is related probably more to the general perinatal state of the child than to any specific pathology (GHOSH AND EMERY, 1970).

**Bile retention syndrome**

Much of the most recent work on specific liver disease is being presented by others, in particular that of alpha-1-antitrypsin but when we have done the tests for this, for cytomegalovirus, for rubella, for syphilis and other known diseases, we have accounted for probably less than a third of children who present with prolonged jaundice (HSIA et al., 1958). Of these, we know that while perhaps a third will completely recover untreated, a third will also succumb with hepatic failure within the following 2 years. These children form the bulk of our present clinical problem. They often have somewhat fluctuant jaundice, their general body state can vary very considerably and their inconclusive liver function tests have been the worry of my clinical friends for years. Many come into hospital on the surgical side and the question always arises as to whether or not there is an element of significant large duct obstruction present that is amenable to surgery. These children present as an Infant Bile Retention Syndrome and the question that always arises is—are they a virus hepatitis, a congenital obstruction of the bile ducts, congenital absence of bile ducts, an inborn error of metabolism, or something else? (HARRIS AND ANDERSON, 1960). My present belief is that most of these cases are probably a combination of several of the factors that were mentioned in the opening paragraph and the structural pathology is also a combination of several factors. The reasons are as follows.

1. The same virus seems to be able to ‘cause’ neonatal hepatitis, congenital absence of bile ducts, and bile duct atresia. This is well established in the case of rubella and cytomegalovirus. A perhaps over simple explanation of this is that the virus affects the liver at different stages of development.

2. Metabolic errors affecting liver cells occur with and without there being bile retention. This has long been known in cases of cystic fibrosis and, more recently, in alpha-1-antitrypsin states.

3. In most of the children with ‘bile duct atresia’, the meconium was normal. Meconium is a mixture of mucus, epithelial cells and bile and it derives its bile from the bile duct and liver. In order to obtain normal meconium, bile excretion must have been functioning normally for a considerable time. This indicates that most bile duct atresias are secondary and acquired states coming on late in intrauterine life, or after birth.

4. Evidence from serial biopsy of the liver lends support to the idea that bile ducts can atrophy after birth. This was first brought home to me in Melbourne with Peter Campbell when, in a sequential series of four biopsies from the same child, the last biopsy showed a ‘congenital absence of bile ducts’ and the first, a ‘hepatitis’ picture. This type of finding is not invariable and must be interpreted carefully as changes can be different in different parts of the same liver.

5. The association of cytomegalovirus lesions with cystic fibrosis. In cytomegalovirus infection of the infant liver, the typical ‘owl’s eye’ lesions are more frequently found in the duct than in the parenchymal cells and in the cases that I have seen, much more marked when the ‘hepatitis’ is associated with cystic fibrosis, which can affect these same ducts in isolation. It would appear that when the ducts are affected by one metabolic abnormality, then the cytomegalovirus becomes more damaging to the duct cells.

6. In biopsies from livers of children with the Bile Retention Syndrome, when the liver lobule shows a variety of lesions, so do the bile ducts and it is not uncommon to see areas of bile duct in which the lining cells appear to be undergoing necrosis. This is usually in empty ducts rather than in those showing bile plugs.

My conclusions from these points are that we must look on the pathology of the Bile Retention Syndrome in a factorial sense and not in terms of finite aetiology. We see livers in different stages of combined disease processes and affecting some parts more than others. Thus, in any liver there is usually both cell damage and bile duct obstruction. Also, a balanced symbiotic virus is likely to become pathogenic in the presence of an inborn error of metabolism in the cells that are again affected by such nonspecific features as E. coli infection of hypoxia (REUBNER et al., 1969).

My plea is—cease to diagnose ‘Neonatal Hepatitis’ and ‘Congenital Bile Duct Atresia’ as finite conditions but look on infants with a Bile Retention Syndrome in a multifactorial way. We may obtain more success by so doing.
Pathology and the bile retention syndrome

Discussion

Dr Emery was asked if he had followed by a series of liver biopsies changes from classical neonatal hepatitis with bile ducts present to that of biliary atresia, either with absent bile ducts in the intrahepatic system or proliferation of the bile ducts in the liver and absence of the external biliary system. Dr Emery replied that he had seen progression from the picture of neonatal hepatitis to that of complete absence of bile ducts. Dr David Danks of Melbourne elaborated on this, reporting on six patients he had followed with clinical and histological neonatal hepatitis who initially had quite obviously bile-containing stools. These infants went on to develop typical clinical features, liver biopsy histology and surgical findings in the porta hepatitis of extrahepatic biliary atresia. In one of these infants an exploratory operation was made when the bile ducts were 'hot, red and oedematous'. Dr Emery reminded the audience that it was usual for infants with biliary atresia to have had bile stained meconium and thus must have had bile flow at some stage in development.
