Summary
A case of primary sideroblastic anaemia is described in which megaloblastic changes in the bone marrow were found to be due to coincidental pernicious anaemia.

The importance is stressed of investigating all cases of macrocytic anaemia by iron staining of the marrow together with estimation of the serum B12 and folate levels.

Introduction
The simultaneous occurrence in the bone marrow of megaloblasts and ring-sideroblasts may result from a variety of causes. In a series of seventeen patients with sideroblastic anaemia, MacGibbon and Mollin (1965) observed megaloblastic change in 54% of cases of primary sideroblastic anaemia, and in 74% of cases of secondary sideroblastic anaemia. The megaloblastic change was attributed to folate deficiency which they detected in 80% of both primary and secondary forms. A favourable response to folate therapy was evident in 40% of the patients. In pernicious anaemia, also, small numbers of ring-sideroblasts are frequently demonstrated in the late megaloblasts although treatment with vitamin B12 results in their rapid disappearance.

A further cause of concurrent sideroblastic and megaloblastic change is illustrated by the following case.

Case report
A woman aged 75 years presented with a history of progressive fatigue, effort dyspnocia, palpitations and episodes of faintness during the previous 9 months, with the recent development of a sore tongue and mouth. There was no relevant family history. She had been treated by her general practitioner for some months with oral iron.

Investigations revealed a haemoglobin of 7.9 g/dl. MCV 130 fl; RBC 1.9 × 1012/l; WBC 3.6 × 109/l (normal differential). The blood film was macrocytic with hypersegmented neutrophils. Bone marrow aspiration showed greatly increased cellularity and gross erythroid hyperplasia with a shift to the left. Development of the red cells was megaloblastic. Iron stains revealed ring-sideroblasts in virtually all early, intermediate and late red cell precursors. Serum iron was 32 μmol/l; TIBC 60 μmol/l; serum folate 4.3 μg/l; red cell folate 62 μg/l; serum B12 25 μg/l; the Schilling test showed 6.1% excretion corrected to 23.7% with intrinsic factor; gastric parietal cell and intrinsic factor antibodies were present in the serum. A Diagnex Blue test showed presumptive evidence of achlorhydria. Barium meal showed mild gastro-oesophageal reflux and no evidence of carcinoma of the stomach. Treatment was started with vitamin B12 250 μg i.m. thrice weekly for the discal forntiff, resulting in a rise of haemoglobin from 7.9 g/dl to 9.8 g/dl. The MCV fell to 114 fl and the RBC rose to 2.5 × 1012/l, but at no stage did the reticulocyte count exceed 3.5%. After 14 days of treatment with vitamin B12 the marrow aspiration was repeated, showing typical appearances of primary sideroblastic anaemia. Erythropoiesis was predominantly normoblastic. Folic acid 15 mg and pyridoxine 100 mg daily were added, and during the next 5 weeks the haemoglobin continued to rise to 12 g/dl. The MCV fell to 98 fl, with a rise of the RBC count to 3.59 × 1012/l. A third marrow aspiration after 7 weeks of treatment showed changes typical of primary sideroblastic anaemia with abnormal ring-sideroblasts in all stages of red cell precursor. She remains well at follow-up two years later.

Discussion
This case would appear to illustrate the coincidental occurrence of primary sideroblastic anaemia with pernicious anaemia.

Until relatively recently the classification of sideroblastic anaemia into primary and secondary types was based upon the simultaneous detection of other diseases. The observations of Hall and Losowsky (1966), however, enable such a classification to be made by examination of the bone marrow alone. Thus in primary sideroblastic anaemia ring-sideroblasts are found in all stages of erythroblast maturation, whereas the early erythroblasts do not
usually exhibit ring forms in the secondary or hereditary types.

From the initial marrow sample the diagnosis of primary sideroblastic anaemia was suggested by the presence of numerous ring-sideroblasts at all stages of erythocyte maturation. At first the megaloblastic changes were attributed to folic acid deficiency, in association with primary sideroblastic anaemia. This opinion was revised at an early stage, however, in view of the Schilling test, serum B₁₂, and antibody results, which were characteristic of pernicious anaemia. The persistence of sideroblastic change in the marrow despite folic therapy and a response to vitamin B₁₂ suggested a concurrent primary sideroblastic anaemia.

The case illustrates the importance of investigating all cases of macrocytic anaemia by iron staining of the marrow together with estimation of the serum B₁₂ and folate levels. The possibility that megaloblastosis and sideroblastosis may be due to separate conditions, as in this case, should be considered particularly when associated with a sub-optimal response to adequate B₁₂ replacement therapy.

Acknowledgments
We wish to thank Dr Eric Jackson for advice and permission to publish details of the case, also Professor M. S. Losowsky and Roger Hall for their helpful criticism. Thanks also to Marion Stainthorpe and Mrs Brenda Day for secretarial assistance.

Recurrent intussusception due to a primary colloid carcinoma of the large bowel in a child

Summary
A case of recurrent colo-colic intussusception due to a primary colloid carcinoma of descending colon with widespread lymphatic involvement in a child, is reported. The unusual mode of presentation and lack of awareness were responsible for a delay of 6 months before the final diagnosis was made. Two years after the operation the patient is well and there is no evidence of clinically detectable secondaries.

Introduction
Intussusception in adults has a predisposing mechanical cause in more than 50% of the patients (Donhauser and Kelly, 1950; Goodall, 1963) but in infants and children a demonstrable lesion, in particular a malignant tumour, is uncommon (Strang, 1959; Dennison and Shaker, 1970). The separation between these two groups of patients has been accepted as the adult patients being over 14 years of age (Goodall, 1963; Elebute and Adesola, 1964).

This report concerns a 12-year-old boy with recurrent colo-colic intussusception due to a primary mucoid carcinoma of the descending colon. The case is of interest because of the rarity of malignant tumours of the colon in childhood and adolescence and the unusual mode of its presentation.

Case report
A 12-year-old schoolboy was admitted to hospital with the complaint of abdominal pain. His symptoms began 6 months before admission with intermittent attacks of colicky lower abdominal pain and distension followed by diarrhoea and passage of blood and mucus per rectum. Between these attacks his general health had been good and he had remained symptom-free. Three weeks before admission, however, some weight loss and diminished appetite were noted by his parents. He had never vomited but had nausea at times. There were no other symptoms or family history of consequence.

On examination, he looked anaemic and appeared tired but had no complaints. He was apyrexial and normotensive. There were no abnormalities in
Sideroblastic and megaloblastic change
