Blood clotting and fibrinolysis in pregnancy

P. W. HOWIE

Summary
During normal pregnancy, the concentrations of many of the clotting factors rise, thereby increasing the potential to generate fibrin. There is also evidence of increased thrombin activity during normal pregnancy which sharply increases during placental separation. Antithrombin III, the main inhibitor of thrombin and activated factor X, shows no compensatory rise during pregnancy but increases during the puerperium.

Plasminogen and antiplasmin concentrations rise during pregnancy but systemic fibrinolytic activity, as measured by the euglobulin lysis time, is markedly depressed during pregnancy; the reduced fibrinolytic activity returns to non-pregnant values very soon after delivery. The loss of fibrinolytic activity is presumed to be loss of plasminogen activator, because when this is added in excess in the urokinase sensitivity test, the fibrinolytic response is normal. The capacity for localized fibrinolytic activity is not lost, however, because fibrinolytic degradation products are slightly raised during pregnancy.

The overall pattern is one of increased coagulant and reduced fibrinolytic capacity during pregnancy which may protect the pregnant woman against the haemostatic challenge of placental separation.

Introduction
The coagulation and fibrinolytic enzyme systems play an essential role in maintaining the integrity of the vascular tree. When a blood vessel is damaged, the coagulation system arrests the haemorrhage and the vessel blockage is subsequently cleared by fibrinolysis. Placental separation represents a profound haemostatic challenge so that it is not surprising that evolution has modified the coagulation and fibrinolytic systems during pregnancy to prevent undue bleeding. A description of how these systems are modified during the course of normal pregnancy now follows.

Coagulation system in normal pregnancy
The coagulation system (Fig. 1) can be activated in two ways, but both have the same final common pathway through the activation of factor X. The first method of activation is the intrinsic system which acts by surface contact when there is endothelial cell injury. This activates factor XII, or Hageman factor, which in turn activates a series of enzymatic reactions involving factors XI, IX, VIII and X. The extrinsic system acts more rapidly when thromboplastin enters the circulation as a result of tissue damage; this, together with factor VII, can activate factor X. Activated factor X combines with factor V and phospholipid derived from platelets to form the prothrombin converting principle. This is responsible for prothrombin to thrombin conversion, which in turn acts on fibrinogen to form fibrin. It is well known that many of the clotting factors rise during pregnancy and these include fibrinogen,
prothrombin and factors VII, VIII, X and XII (Todd et al., 1965).

Fibrinogen levels in pregnancy

The coagulation factors tend to rise during the third trimester and the results of a recent study on the fibrinogen levels of 60 primigravidae is shown in Fig. 2 (Condie and Ogston, 1976). Before delivery the fibrinogen concentration is about 50% above the non-pregnant value. Bearing in mind the increase in circulating blood volume, there is about double the amount of fibrinogen available to the pregnant woman at delivery compared to the non-pregnant state. After delivery there is a secondary rise in fibrinogen followed by a return to normal.

Thrombin activity in pregnancy

The raised levels of clotting factors in pregnancy do not necessarily mean that there is increased clotting activity during pregnancy. There has been increasing interest in methods designed to measure thrombin activity more directly during pregnancy. One of the principal actions of thrombin is to split fibrinopeptides from negatively charged fibrinogen to form fibrin monomer, which becomes positively charged. Fibrin monomer and native fibrinogen then combine to form fibrin-polymer chains which may remain in soluble form within the circulation. These polymer chains may later be deposited as insoluble fibrin and, under the influence of factor XIII, there is cross-linking which renders the reaction irreversible. The presence of circulating soluble fibrin polymer can be detected by the relatively new technique of fibrinogen chromatography. It has been shown that there is a small rise of fibrin polymer complexes during normal pregnancy which is strong evidence of low-grade thrombin activity (McKillop et al., 1976).

Factor VIII antigen-activity ratio

When thrombin is formed, the first molecules act upon factor VIII to generate more coagulant activity and a second more vigorous burst of thrombin production. When thrombin activates factor VIII, the factor VIII molecule loses its coagulant activity but retains its antigenic potential. Therefore, when the factor VIII antigen-activity ratio rises, this is suggestive evidence of increased thrombin activity. A rise of factor VIII antigen-activity ratio has now been described (Van Royen and Ten Cate, 1973; Thornton and Bonnar, 1977) confirming the picture of increased thrombin-like activity in some women during normal pregnancy (Fig. 3). At the time of placental separation, studies on umbilical vein blood have shown a profound activation of coagulation (Bonnar, McNicol and Douglas, 1970).

Antithrombin activity during pregnancy

The main inhibitor of thrombin is antithrombin III which is an $\alpha_2$-globulin (mol. wt 60,000) and which also inhibits activated factor X. The clinical importance of antithrombin III is demonstrated by the greatly increased risk of thrombo-embolism in
patients with an inherited deficiency of this protein (Egeberg, 1965). Despite the increased potential to form thrombin in pregnancy, there is no compensatory rise in antithrombin III (Fig. 4) (Howie et al., 1975). Following delivery, antithrombin III levels rise during the first week of the puerperium which may reduce the risk of thromboembolism after delivery.

**Fig. 4.** Plasma antithrombin III before and after delivery (n=15). Mean levels ± s.d. The dotted lines show the non-pregnant range.

Antithrombin III is most probably identical to heparin co-factor whose activity is greatly potentiated by heparin. The antithrombin III values in pregnancy are consistent with the observation that there is relative resistance to heparin during pregnancy which rapidly subsides after delivery (Bonnar, 1976).

**Platelets**

The platelet count does not change during pregnancy but rises during the first week of puerperium before returning to non-pregnant values 6 weeks after delivery (Howie, Prentice and McNicol, 1971). Many tests of platelet function have been carried out during pregnancy, including platelet adhesiveness, platelet aggregation (Howie et al., 1971), serotonin release (Whigham et al., 1978) and platelet turnover (Wallenburg and van Kessel, 1978) but none of these tests deviated from the non-pregnant values. In summary, platelet behaviour shows little, if any, change during pregnancy from the non-pregnant state.

**Fibrinolytic system**

When fibrin is deposited, plasminogen is incorporated into the substance of the deposit to ensure its subsequent lysis. This lysis occurs when plasmin is formed following the action of activator upon the plasminogen. Activation may come through different routes, namely factor XII, tissue activator or vascular endothelium (Fig. 5). The inhibitors of activator and plasmin are present in high concentrations within the blood so that plasmin is rapidly neutralized in the free circulation. Within a fibrin clot, the situation is different; inhibitors are largely excluded so that activation of plasminogen to plasmin and lysis of fibrin to degradation products (FDPs) will take place when activator diffuses into the clot. Distinction must therefore be made between systemic and localized fibrinolytic activity.

**Euglobulin lysis time**

One of the most dramatic observations in pregnancy is the profound depression of fibrinolytic activity as measured by the euglobulin lysis time which returns to normal within 30 min of delivery (Shaper, MacIntosh and Kyobe, 1966). In this test (Fig. 6), the euglobulin precipitate is prepared which contains fibrinogen, plasminogen and activator with the inhibitors excluded. The euglobulin precipitate is resuspended and clotted with thrombin and the lysis time is then measured. Since fibrinogen and plasminogen are present abundantly in pregnancy, the long lysis times in pregnancy are presumed to be due to diminished activator activity.

When activator activity is provided in excess, as in
the urokinase sensitivity test (Fig. 7), the fibrinolytic response is normal (Howie et al, 1971). This is controlling the coagulation and fibrinolytic systems in pregnancy. It has been shown that the return of fibrinolytic activity to normal depends more upon delivery of the placenta than delivery of the fetus (Astedt, 1972). Foley, Clayton and McNicol (1977) have recently compared the haemostatic mechanisms in umbilical vein and artery blood; the vein, in comparison to the artery, showed increased clotting and decreased fibrinolytic activity, suggesting a regulatory role for the placenta.

In summary, the pregnant woman shows an enhanced capacity to generate fibrin and an increase in thrombin-like activity without the balance of increased antithrombin activity. In addition, there is suppression of systemic fibrinolytic activity although the capacity for localized fibrinolysis is not abolished. This shift in balance may encourage more effective haemostasis but may also predispose the pregnant woman to the complications of thrombo-embolism or intravascular coagulation.

further evidence that deficient activator activity is responsible for the decreased systemic fibrinolytic activity in pregnancy.

Plasminogen levels are raised in pregnancy (Bonnar, McNicol and Douglas, 1969) but these are counter-balanced by a similar rise in antiplasmin activity (Fig. 8). It is clear that localized fibrinolytic activity is not completely abolished because the capacity of the pregnant women to form FDPs is maintained and the levels in late pregnancy may be slightly raised over the non-pregnant range (Woodfield et al., 1968).

**Role of the placenta**

The placenta appears to play a critical role in
