Summary
Relatively simple and rapid procedures have been developed for evaluating the local efficacy of vaginal antifungal agents in vivo in a vaginal candidiasis model in ovariotomized rats. The results of this investigation indicate that the model and methods described are quite suitable for screening potential antifungal substances and for assessing the chemotherapeutic effectiveness of new antifungal agents and formulations before carrying out clinical studies.

Introduction
Vaginal candidiasis is a common and chronic ailment in women of child-bearing age. The incidence of this vaginal infection has increased considerably in recent years with the more frequent use of antibiotics and oral contraceptives. Pregnancy and diabetes are thought to be specific predisposing factors. While a few good antifungal agents, formulated as vaginal products, are available for treating vaginal candidiasis, there is still a need for safer and more efficacious vaginal preparations. Consequently, efforts to discover new and better antifungal agents and to prepare more effective vaginal formulations have continued. The authors recently developed relatively simple and rapid test procedures for evaluating the efficacy of new vaginal antifungal agents and formulations using an experimental vaginal candidiasis in ovariotomized rats.

Materials and methods

Animals
Female, ovariotomized Charles River CD rats (Sprague-Dawley derived) weighing 190±10 g were used in all studies. Pairs of rats were caged on wire in temperature- and humidity-controlled rooms and permitted food and water ad libitum.

Test organism
Candida albicans SC 5314, a clinical isolate maintained in the departmental culture collection, was employed to establish the experimental infection. Inocula for infection were prepared by harvesting the growth from Sabouraud’s dextrose agar slants of C. albicans obtained after 24–48 hr incubation at 37°C and making suspensions containing 10⁸ colony-forming units (CFU)/ml.

Establishment of the experimental infection
Rats were pretreated with 0.5 mg of progesterone and 0.5 mg of oestradiol valerate administered subcutaneously to induce oestrus. Confirmation of oestrus was made by microscopic examination of vaginal smears. Beginning 2 days after hormonal treatment, rats were inoculated intravaginally on 2 successive days with 10⁷ CFU of C. albicans contained in a 0.1 ml inoculum. The presence of vaginal candidiasis in inoculated rats was confirmed microscopically and culturally.

Quantitation of C. albicans in the experimental infection
At various intervals after infection, an estimate of the number of candidal CFU in the vagina was determined by culture of saline washings obtained by vaginal lavage. Each wash suspension was appropriately diluted and then plated on Mycosel agar (BBL) using conventional plating techniques. Plates were incubated for 48 hr at 37°C, after which colony counts were performed using an electronic colony counter. For a few experiments, groups of rats were sacrificed at various intervals after infection, and the genital tract of each rat removed in toto. Each organ was dissected into 3 parts; the vagina, the cervix (including the body of the uterus), and the uterine horns. The various tissues were homogenized individually and appropriate dilutions of each homogenate were plated on Mycosel agar. For histological studies, the intact genital tract or the vagina alone was placed in 10% formalin, embedded in paraffin, sectioned and stained with haematoxylin and eosin or periodic acid-Schiff stain.
Chemotheerapeutic studies

The following commercial antifungal products were studied: AVC cream, 15% sulphamethamide and 0.2% aminocarb (Merrel-National Laboratories); Betadine vaginal gel, 10% povidone-iodine (Purdue Frederick Co.); Candicin vaginal ointment, 0.6 mg/g candidin (Schmid Laboratories); Gyne-Lotrimin vaginal tablets, 100 mg clotrimazole/ tablet (Dellbay Pharmaceuticals); Monistat 7 vaginal cream, 2% miconazole nitrate (Ortho Pharmaceutical Corp.); mycostatin cream, 100 000 u./g nystatin (E. R. Squibb and Sons); Sporostacin cream, 1% chlordantoin and 0.05% benzalkonium chloride (Ortho Pharmaceutical Corp.); and Tricandil candeleute vaginali, 25 000 u. partีcin methyl ester/ovule (Società Prodotti Antibiotici).

Three days after the final intravaginal inoculation of C. albicans, rats were randomly divided into groups of 10–20 animals and treatment was begun. Approximately 0.1 g of a cream, ointment or gel formulation was placed high in the vaginal vault by means of a ball-tipped needle and syringe. Formulations were administered twice daily for 3 days. Solid dosage forms (tablets and ovules) were inserted intravaginally in reformulated rat-size portions once daily for 3 days. Forty-two hours after the final treatment vaginal washings were obtained from all rats, and appropriate dilutions were cultured as described above. The response of the infection to chemotherapy was determined by comparing the mean candidal count for each treatment group to that obtained from a placebo-treated control group.

Detection of residual drug activity

Vaginal washings, obtained from rats 42 hr after the termination of therapy were passed through 0.45-μm membrane filters before being tested for drug activity. Aliquots of washings were incubated at 37°C in the presence of known concentrations of C. albicans (10⁸ to 10⁹ CFU/ml). At various intervals during the incubation period, samples were removed from each mixture, diluted if necessary, and plated on Sabouraud’s dextrose agar. The mean concentration of candidal CFU determined for each group of test mixtures was compared to that obtained with control mixtures containing washings from a placebo-treated or untreated group of rats. Filtrates of washings from treated groups were sometimes plated directly on agar plates along with an inoculum containing a known concentration of C. albicans to determine if there was drug carry-over.

Results

Experimental infection

The vaginal infection of ovariectomized rats with C. albicans SC 5314 was studied macroscopically, microscopically and culturally. Grossly, no signs of infection were evident throughout the course of several long-term experiments. Vaginal discharges or plaques on the vaginal mucosa, commonly found in human candidal vaginitis, were not observed. By microscopic examination 24 hr after infection the vaginal mucosa was found to exhibit the classical signs of oestrus; marked hyperkeratosis and pronounced exfoliation of the stratum corneum. Blastospores of C. albicans were observed in the superficial layers of the vaginal mucosa and lying free in the vaginal cavity. A slight inflammatory response was noted in the subcutaneous tissues. By 72 hr after infection the concentration of blastospores appeared to have diminished but a few mycelial elements were observed in the stratum corneum.

The magnitude and extent of vaginal colonization by C. albicans was followed for several weeks using culture of vaginal washings to quantitate candidal CFU (Fig. 1). The peak concentration of C. albicans was found 24 hr after infection; however, during the remainder of the first week, the candidal count fell rather precipitously; thereafter, the count declined more gradually. By day 30, C. albicans was seldom isolated from vaginal washings. Small numbers of candidal cells were isolated from extravaginal sites in the genital tract at various intervals after infection.

Sampling methods

Before employing the acute vaginal candidiasis model for chemotherapeutic studies, various methods of quantitating vaginal C. albicans were investigated. The use of swabs for sampling the vaginal candidal count was found to be unsatisfactory. Homogenization and culture appeared to be the method of
choice for determining the vaginal candidal count. However, this method required much effort and was quite time consuming. Thus, vaginal lavage and culture, which has been widely used for clinical studies, was investigated as a potential method for sampling. The accuracy of the vaginal lavage and culture method of sampling was evaluated by comparing results obtained by that method to those obtained using vaginal homogenization and culture (Table 1). As expected, higher candidal counts were consistently obtained from cultures of vaginal homogenates. However, neither individual counts from vaginal homogenates nor the mean count of a group were seldom more than one log10 higher than comparable counts obtained by cultures of vaginal washings. Thus, it appeared that sampling by vaginal lavage, while not as accurate as the homogenization technique, nevertheless demonstrated somewhat similar variation and a sufficiently high recovery rate to warrant its routine use.

Response to chemotherapy
In order to determine if the experimental infection would respond to chemotherapy, various commercial antifungal formulations were evaluated. The results of a typical experiment are shown in Table 2. As can be seen, the infection did respond to chemotherapy, exhibiting different responses to different products. It should be noted that the primary evaluation of efficacy is based on the mean candidal count and the resulting per cent. reduction relative to the placebo control. These results and others, not shown here, indicated that the model infection could be used for chemotherapeutic studies. However, in order fully to characterize the model and its response to chemotherapy, dose–response studies with clotrimazole, nystatin, and miconazole were conducted. Good dose–response curves were obtained with the 3 antifungal agents (Fig. 2).

Residual drug activity
Experiments were carried out to ensure that any response of the experimental infection to chemotherapy was due to actual drug efficacy resulting from treatment and not to residual drug or drug–carry-over that would reduce candidal counts during the plating procedure. Cell-free filtrates of washings from rats treated with each drug evaluated were tested for residual drug activity and/or drug carry-over to the culture medium. In no instance was there any suggestion that these possibilities might be occurring in the evaluation of various chemotherapeutic agents.

Discussion
In order to identify and evaluate substances that may be effective as vaginal antifungal agents in humans, experimental infections in laboratory animals have been developed. Scholer (1960) reported on the establishment and practical applications of a vaginal candidiasis model in ovariectomized rats. A similar model in mice was described by Taschdjian, Reiss and Kozinn (1960), but it remained for Wildfeuer (1974) to adapt the model to chemotherapeutic studies. Because several investigators have demonstrated the utility of the rat model of vaginal candidiasis in studying antifungal efficacy (Mizuba et al., 1974; Polak, 1978), the present authors selected the model for further characterization and subsequent determination as to its potential as a screening tool for potential antifungal agents.

The results obtained with several known antifungal agents, when evaluated in the model infection using test procedures such as the 3-day treatment schedule, culture of vaginal washings, and dose–response studies, indicate that relatively simple, rapid, and effective means of screening have been developed. In addition, it was found that statistical analyses of data generated with the test procedures and the model and the incorporation of the findings into the experimental design can lead to a more significant evaluation of potential antifungal agents. For example, data from dose–response studies can be utilized to indicate sample size requirements or to

determine by means of a parallel line assay the potency of a test drug relative to a reference drug.

Scholer (1960) reported that the vaginal candidiasis model in ovariectomized rats responded to chemotherapy with antifungal agents when they were administered systemically or locally. In the present study it was found that the model infection responded to a wide variety of antifungal agents applied locally in cream, ointment or gel formulations. It was also demonstrated that the model infection would respond to chemotherapy with both solid and liquid drug formulations (Mizuba et al., 1974). Consequently, one aspect of the rat model that enhances its effectiveness is its capacity to respond to chemotherapy with various types of antifungal agents administered by different routes and in diverse dosage forms.

As with most model infections, there are certain differences between the experimental infection and the natural infection. For example, the experimental infection is rather acute and self-limiting when compared to the chronic, persistent ailment found in women; the experimental infection does not exhibit vulval involvement, vaginal discharges, or mural plaques as is often observed in women; the vaginal pH in the experimental infection is less acidic than in the natural infection; and the normal flora and vaginal mucosa are somewhat different in the 2 hosts. On the other hand, the experimental infection somewhat resembles the natural infection in that candidal elements are localized superficially in the vagina, both yeast and mycelial forms of C. albicans are found, and a microenvironment similar to that found in humans (mixed bacterial flora, vaginal secretions, and pH, etc.) is present. The rat model provides some of the same variables encountered clinically; individual variations in vaginal size and shape, ecosystems, responsiveness to chemotherapy, and retention of drugs.

While differences between the experimental and natural infection do exist, the model does meet various criteria for use as a successful screening tool: (i) the infection is easily produced and quantitated, (ii) the infection is responsive to clinically effective drugs, (iii) the infection can demonstrate dose-response relationships, and indicate relative potency, and (iv) results from chemotherapeutic studies in the model appear to have some predictive value for clinical studies. Thus, using the test procedures described earlier, the vaginal candidiasis model would appear to have a definite role as a screening tool in the preclinical evaluation of potential antifungal agents.
