Summary
A Chinese patient with the incomplete form of pachydermoperiostosis is described. Brief comments on the diagnosis, familial occurrence and management are given.

Introduction
Pachydermoperiostosis is a syndrome characterized by finger clubbing, periosteal new bone formation especially over the distal ends of long bones, and coarsening of the facial features, with thickening, furrowing and oiliness of the skin of the face and forehead. The first reported cases were the Hagner brothers, who had typical features of this syndrome. They were first described by Friedreich (1868), and later by Erb (1887) and Virchow (1889), who diagnosed the condition as acromegaly. It was only 45 years ago that pachydermoperiostosis was first recognized as a distinct entity by Touraine, Solente and Golé (1935), and thus frequently referred to as 'Touraine-Solente-Golé syndrome'. It has since been reported from Europeans, Japanese (Ota, 1931), African Negroes (Findlay and Oosthuizen, 1951), American Negroes (Vogl and Goldfischer, 1962), Hindus (Carruthers, 1943) and South American Indians (Marroquin, 1941) but as far as the present authors are aware, only one case has been reported from a Chinese (Leong, Ng and Tay, 1976). They now report details of a second Chinese patient, the first such patient to be described from Hong Kong.

Case report
A 16-year-old male student first attended Nethersole Hospital in July 1976 complaining of painless enlargement of the tips of his fingers and toes for the past 3 years, with significant progression over the past year. On direct questioning, he admitted that his wrists and ankles had also become bigger. There was, however, no arthralgia or bone pain. He had been troubled by pimples on his cheeks for 7 months. He was the tallest and heaviest among existing members of his family. Family history of clubbing or arthralgia was negative. He was a non-smoker and had no respiratory symptoms. There was no history of headache or visual disturbance. Initially he had attended a clinic at another hospital, where the diagnosis of acromegaly had been made.

On examination, he measured 182 cm in height (>97th centile) and 66 kg in weight (95th centile). There was no cyanosis and secondary sexual characteristics were well developed. Hyperhidrosis was not present. His fingers and toes showed marked clubbing, giving rise to the typical spade-like hands and feet and the watch-glass nail plates (Fig. 1). His ankles and wrists were enlarged but without signs of arthritis. His forehead had prominent transverse folds and the naso-labial folds were deep, imparting an expression which was anxious and mature for his age (Fig. 2). The skin of the face was thickened, oily and pitted with scars of acne. There was however no thickening or furrowing of the scalp (cutis verticis gyrata). No other abnormal signs were noted.

The following investigations were within normal limits: haematological profile, ESR, blood urea, serum electrolytes, serum bilirubin, alkaline-phosphatase and transaminases, an oral glucose tolerance test extended up to 5 hr, serum calcium, inorganic phosphate and serum protein electrophoresis. VDRL test was negative. Serum thyroxine level was 120 nmol/l (normal 70–160 nmol/l). Fasting growth hormone was 1·01 μg/l (normal 1·0–10·0 μg/l). Chromosome study showed normal karyotype with XY sex chromosomes.

The radiological findings were of interest. X-ray of the hands and wrists (Fig. 3) revealed subperiosteal new bone formation at the 4th and 5th metacarpals and all proximal phalanges, with thickened cortical bone at the distal end of the ulnae. Soft tissue thickening and clubbing of fingers were also evident. X-ray of the feet and ankles showed thickened cortex of the metatarsals and proximal phalanges. Loss of normal contour and irregular thickening of cortical bone were present along the shaft of the fibulae and tibiae (Fig. 4). X-rays of the chest, skull and heels were normal.

The diagnosis of pachydermoperiostosis was made on the basis of clinical and radiological findings, and reassurance given. Follow-up to date (June, 1980) showed no further progression of his condition.

Discussion
The age and sex of the patient, the gradual onset of symptoms, the clinical features of marked clubbing,
enlargement of distal ends of extremities and coarsening of facial features, suggest the diagnosis of pachydermoperiostosis (idiopathic hypertrophic osteoarthopathy). This is confirmed by the radiological picture of irregular subperiosteal new bone formation along the tubular bones. Touraine et al. (1935) distinguished 3 forms of this condition—the 'complete form' with pachydermia and pachyperiostosis; an 'incomplete form' without scalp involvement; and a 'forme fruste' in which clubbing and thickening of the face, scalp or both, are present, but periosteal changes are absent or minimal. In the absence of cutis verticis gyrata, the present patient fits into the 'incomplete form'.

Hypertrophic pulmonary osteoarthopathy, which also gives rise to clubbing and subperiosteal new bone formation, has to be excluded. It has long been considered that coarsening of facial features and scalp is diagnostic of idiopathic hypertrophic osteoarthopathy; however, this may also appear in association with intrathoracic tumours (Hammarsten and O’Leary, 1957). Thus, it is impossible to distinguish between these 2 forms of hypertrophic osteoarthopathy by the appearance of the patient alone. The features which point to the pulmonary form are: an older age of onset, an acute onset associated with pain in the extremities, and the presence of neoplastic or suppurrative intrathoracic diseases.

To the unwary, the acromegaloid face may lead to the diagnosis of acromegaly or gigantism. However, a careful assessment will show that the soft tissue overgrowth is restricted to the extremities and the face, that the skeletal overgrowth is not generalized and that the local and secondary hormonal effects of pituitary tumour are absent.

Other conditions which may cause confusion in the diagnosis are thyroid acropachy, leprosy, rheumatoid arthritis, syphilitic periostitis and Paget’s disease of bone.

Familial occurrence is common and has been observed in more than 50% of the reported cases. The disorder is inherited as an autosomal dominant trait, with marked variability in expression, phenotypically more severe in males (Rimion, 1965). Chromosomal abnormalities of XYY trisomy have been observed in a patient and his son, both having idiopathic osteoarthopathy (Tzoneva-Maneva, Bosajieva and Petrov, 1966). Either simple hereditary clubbing or cutis verticis gyrata can occur within families and independently of pachydermoperiostosis. It is possible that they may represent monosymptomatic forms of pachydermoperiostosis (Marroquin, 1941). In the present patient there were no chromosomal abnormalities and there was no family history of pachydermoperiostosis, clubbing or cutis verticis gyrata.

Pachydermoperiostosis has a self-limiting course, and progression stops at the end of adolescence. There is no curative treatment for the skeletal abnormalities. Mild analgesics may be given for pain due to sub-periosteal new bone formation. For correction of gross disfigurement, plastic and reconstructive surgery may be indicated. Otherwise, reassurance is all that is required. Clinical recognition of pachydermoperiostosis is important, since...
