Summary
A patient is described who developed gastrointestinal amyloidosis complicating psoriatic arthropathy. The presenting symptom was progressive dysphagia due to oesophageal involvement. Other clinical features included gastric ulceration with melaena, intestinal pseudo-obstruction and evidence of impaired renal function. The oesophageal symptoms improved after endoscopic dilatation of the cardia. Colchicine was used in an attempt to slow down progression of the condition.

Introduction
Secondary amyloidosis is associated with a variety of neoplastic and chronic inflammatory disorders (Kyle and Bayrd, 1975), but has rarely been described as a complication of psoriatic arthropathy (Moise, Asch and Imbs, 1965; Ferguson and Downie, 1968; Qureshi et al., 1977). The authors have recently seen a patient with long-standing psoriasis and a seronegative arthritis, who presented with a severe disturbance of gastrointestinal motility and who proved to have extensive amyloidosis.

Case report
A 35-year-old man was admitted to hospital in 1980 with a 3-month history of heartburn and progressive dysphagia. He had had severe psoriasis for 17 years, and had been treated with systemic and topical corticosteroids since 1966. Methotrexate, azathioprine, dapsone and hydroxyurea had been tried at different times, all with little benefit. In 1976 he developed a progressive arthritis involving the hands, wrists, elbows, ankles, knees, hips and sacro-iliac joints; a right hip replacement was performed in 1978. In 1977 he was started on methoxsalen 40 mg twice weekly with long-wave ultra-violet light exposure (PUVA therapy); this produced some improvement in his skin condition, and by 1980 he had received almost 200 such treatments. Early in 1979 he was admitted to hospital for intensive therapy of an exacerbation of his skin disease. He had noted alternating diarrhoea and constipation for the previous month. Shortly after admission he developed abdominal pain, vomiting and a fever; plain abdominal X-rays suggested small bowel obstruction. At laparotomy the jejunum and ileum were found to be distended but there was no other abnormality. The abdomen was closed and a prolonged ileus lasting 8 weeks followed.

In 1980 he began to experience difficulty in swallowing; which was worse for solids than for liquids. He had noticed particularly severe retrosternal discomfort after eating fruit or drinking fruit juice, and had avoided these for several months. His dentition was poor and his gums bled easily. He had become constipated and had lost about 12 kg in weight.

On examination, he was a thin man with widespread psoriasis and nail pitting. He had extensive joint disease consistent with psoriatic arthropathy, and a right-sided Charnley hip prosthesis. His gums were swollen and friable. Abdominal examination was unremarkable apart from the presence of a poorly healed surgical scar. BP was 140/80 mmHg with no postural change and the Valsalva response was normal. His speech was slightly slurred but there was no other abnormality in the central nervous system and no evidence of a peripheral neuropathy.

A few days after admission, the patient began to pass melaena stool and became clinically anaemic.

Laboratory investigations
Initial Hb was 13-7 g/dl, falling to 8-2 g/dl after the gastrointestinal haemorrhage. White cell count, platelet count and haematological indices were normal, but the ESR was 68 mm/hr. Plasma biochemistry was normal apart from a blood urea of

9.2 mmol/l. Creatinine clearance was 42 ml/min, and 1.14 g of protein was excreted in the urine over 24 hr. No Bence-Jones protein was found, but the urine did contain small amounts of free kappa and lambda light chains. Prothrombin time and liver function tests, including plasma albumin, were normal. Serum IgA was elevated at 8.3 g/l but the other immunoglobulins were normal; serum protein electrophoresis showed a slightly raised α₂-globulin but no evidence of a paraprotein band. Serum and red cell folate, and serum B₁₂ concentrations were normal. All thiamine deficiency. Leucocyte ascorbic acid was below detectable levels, and red cell transketolase activity was reduced, suggesting thiamine deficiency. Serological tests for antinuclear factor and rheumatoid factor were negative. The HLA-B₂₇ histocompatibility antigen was not detected.

Radiology
A barium swallow had been arranged by the patient's family doctor and was reported to show the appearances of achalasia of the cardia (Fig. 1). A cineradiographic examination of swallowing confirmed that the oesophagus was aperistaltic throughout its entire length and that the lower sphincter failed to relax normally.

The jejunum and ileum were examined by an intubation small bowel meal. Peristaltic activity was much reduced throughout the small intestine, but the luminal calibre and the appearances of the mucosal folds were normal.

Chest X-ray was normal, but plain abdominal films showed bilateral sacro-iliiitis. An i.v. urogram was unremarkable.

Endoscopic findings
A fibreoptic upper gastrointestinal endoscopy was performed shortly after the episode of melaena. The oesophagus was grossly dilated and inflamed, with large amounts of partly digested food material in the lumen and patches of thrush on the mucosa. The oesophago-gastric junction was traversed easily, and the stomach was also seen to contain large volumes of undigested food. Peristaltic activity was markedly less than normal and there was an extensive gastritis. The antrum contained 3 small ulcers, one of which was covered by an adherent blood clot. The pylorus and duodenum looked structurally normal but, again, peristaltic movements were sparse.

Histology
Endoscopic biopsies from the oesophago-gastric junction showed infiltration of the mucosa with lymphocytes and polymorphonuclear leucocytes, with superficial ulceration and a few fungal hyphae. Within the submucosa were numerous fundal-type glands which were surrounded by acellular eosinophilic material (Fig. 2). After Congo red staining this showed the birefringence under cross-polarized light which is typical of amyloid. The gastric ulcers were histologically benign. The walls of many of the small blood vessels in the gastric and duodenal mucosa were completely replaced by amyloid. Amyloid was also present as aggregates in the lamina propria and muscularis mucosae of both organs. Electron microscopy of the duodenal deposits confirmed their fibrillar nature (Fig. 3).

A rectal biopsy was subsequently found to contain small amounts of amyloid material. The papillary vascular plexus of skin from non-psoriatic areas was also affected.

A mesenteric lymph node and a rectal biopsy obtained at the laparotomy 18 months previously were reviewed. Both of these had been reported as
showing no abnormality on routine histological staining, but both in fact contained substantial amyloid deposits.

Treatment and progress
After the gastrointestinal bleed, the patient was transfused and started on cimetidine. His oesophageal candidiasis was treated with a nystatin suspension. For 2 weeks he was fed enterically using a fine-bore nasogastric tube. When his general nutritional state had improved and his ascorbic acid deficiency had been corrected, the oesophago-gastric junction was gently dilated to 58-F (Charrière) gauge by the endoscopic Eder-Puestow technique (Price, Stanciu and Bennett, 1974), with improvement in his swallowing. He was discharged from hospital taking colchicine 0.5 mg twice daily in an attempt to inhibit further amyloid deposition. He has remained well during the succeeding 6 months, apart from a mild flare-up of his skin condition and a second small gastrointestinal haemorrhage which settled with transfusion and a further course of cimetidine.

Discussion
Most prior reports suggest that the gastrointestinal tract is involved in well over 50% of the patients with secondary amyloidosis (Dahlin, 1949; Fentem, Turnberg and Wormsley, 1962; Gilat, Revach and Sohar, 1969). The clinical manifestations of amyloid infiltration include malabsorption (Herskovic, Bartholomew and Green, 1964; Gilat and Spiro, 1968), infarction with perforation (Gilat and Spiro, 1968; Brody, Westlake and Laster, 1964; Griffel, Man and Kraus, 1975), intestinal obstruction (Kyle and Bayrd, 1975) and protein-losing enteropathy (Jarnum, 1965; Hunter et al., 1979). Motility disturbances and bleeding, both of which this patient demonstrated, are particularly common. Oesophageal amyloidosis may result in dysphagia while small intestinal involvement can cause episodic pseudo-obstruction (Gilat and Spiro, 1968; Legge, Wollaeger and Carlson, 1970). Although muscle infiltration has been suggested as the factor responsible for impaired motility, it is possible that neural dysfunction may contribute to this abnormality in some cases (Gilat and Spiro, 1968; French et al., 1965; Battle et al., 1979). This patient showed extensive amyloid deposition in the muscularis mucosae of both stomach and small bowel, but the superficial nature of the tissue biopsies did not allow the authors to assess involvement of the autonomic nerve plexuses. Ulceration of mucosal...
areas containing amyloid material is probably due to local ischaemia secondary to vascular occlusion, and commonly leads to gastrointestinal haemorrhage (Gilat and Spiro, 1968; Brandt, Cathcart and Cohen, 1968). In the present case, the base of the bleeding gastric ulcer contained many blood vessels, the walls of which were almost completely replaced by amyloid.

Skin infiltration has been described in about 40% of patients with secondary amyloidosis (Rubinow and Cohen, 1978); a biopsy from a non-psoriatic area in the present patient revealed amyloid deposits in the small cutaneous vessels. In a recent paper, Greene and Cox (1979) reported that amyloid was frequently found in the skin of patients with psoriasis who had been treated for prolonged periods with methoxsalen and long-wave u.v. irradiation, and suggested that it might represent a complication of this form of therapy. However, none of their patients had clinical evidence of systemic involvement, and the deposits occurred as aggregates in the superficial corium rather than in the perivascular distribution shown by this patient. It therefore seems unlikely that the PUVA treatment was responsible for the development of extensive amyloidosis in the present case.

Because of the heavy amyloid deposition found at the cardia, and also because of the patient's severe ascorbic acid deficiency, the authors were unwilling to treat his dysphagia surgically or by vigorous hydrostatic dilatation of the lower oesophagus. Dysphagia can be temporarily relieved in patients
with achalasia and similar motor disorders by passage of olive dilators through the cardia (Vantrappen and Hellemans, 1980). Eder-Puestow dilatation via a fiberoptic oesophagoscope produced considerable improvement in this patient’s swallowing, and this has been maintained over the subsequent months.

In experimental animals, casein-induced synthesis of amyloid can be inhibited by colchicine, possibly because the drug blocks the production of an amyloid-accelerating factor by reticuloendothelial cells (Shirahama and Cohen, 1974; Kedar, Greenwald and Ravid, 1976). In theory, colchicine may be beneficial in human amyloidosis by arresting or slowing down progression of the condition, but firm evidence on this point is lacking.

Previous studies suggest that this patient’s prognosis is likely to be poor. He has marked proteinuria and an impaired creatinine clearance, which imply the presence of renal amyloidosis. The general experience has been that survival in such cases is usually a matter of a few months from the time of diagnosis (Brandt et al., 1968; Legge et al., 1970; Kyle and Bayrd, 1975).
