Summary

A patient who developed a bullous skin eruption associated with carbamazepine overdosage is described. The authors believe this previously unreported phenomenon to be of clinical importance. Carbamazepine should be considered in the differential diagnosis of drug-induced coma with associated bullous lesions.

KEY WORDS: carbamazepine overdose, bullous skin eruption.

Introduction

Bullous skin lesions have been described in association with barbiturate-induced coma (Beveridge and Lawson, 1965) and also with several other drugs (Anonymous, 1981). The lesions characteristically occur at sites of trauma, and within 24 hr of ingesting the drug (Mandy and Ackerman, 1970). The authors wish to report a case of bullous skin eruption as a result of carbamazepine overdosage.

Case report

A 68-year-old female was brought to the Casualty Department, having been discovered at home in a semi-conscious state. On examination, she was drowsy and disorientated in time and place, her pulse was 90/min and regular, and the blood pressure was 90/70 mmHg. There was generalised increase in tone, and hyper-reflexia with equivocal plantar responses bilaterally. Bullous lesions were present on the dorsal aspects of both feet and over the right lower tibia. Further lesions developed over the left iliac crest and on the lateral aspects of the left breast and left forearm during the subsequent 5 hr. The lesions varied in size from 0.5 cm to 3 cm in diameter, each developing initially as an erythematous patch which progressed within one to 2 hr to form a bulla containing clear fluid and surrounded by a narrow rim of erythema.

Initial investigation revealed that the urea and electrolytes, arterial blood gas analysis and blood sugar concentration were within normal limits and barbiturates were not detected in plasma. Following standard supportive therapy, the patient regained full consciousness within the subsequent 24 hr. She then disclosed that she had been prescribed carbamazepine for facial pain some weeks previously. She had taken only a few tablets intermittently, until 16 hr before admission when she had swallowed approximately 40 tablets. Unfortunately, serum from the time of admission was not available for carbamazepine assay.

Serological examination showed a positive anti-nuclear factor at a titre of 1/640 and a weakly positive R.A. latex test. The Rose Waaler titre was less than 1:4 and DNA binding was 25 units anti-DNA/ml (reference range—up to 25 units anti-DNA/ml). A biopsy of the lesion overlying the iliac crest was taken and submitted for histological examination. Direct immunofluorescence study was not carried out on the biopsy and indirect examination using the patient's serum was negative. The skin showed an area of suprapapillary bulla formation rooted by necrotic epithelium. The dermis was congested with fibrinoid necrosis in an occasional small vessel wall and fibrin and acute inflammatory cells were present.

Discussion

Carbamazepine is in common usage as an anti-convulsant and in the management of trigeminal neuralgia. Toxic effects in therapeutic dosage are relatively common, and skin reactions, including exfoliative dermatitis, urticaria, Stevens-Johnson syndrome and toxic epidermal necrolysis, are said to occur in 3% of patients (Crill, 1973; Roberts and Marks, 1981). The pattern of reaction occurring in our patient has not, to our knowledge, been previously documented with carbamazepine overdosage, although a bullous skin eruption has been described with imipramine, a chemically related compound.

and occasionally in unconscious states without drug ingestion (Freeman and Raza, 1965). A lupus erythematosus-like phenomenon has been described with therapeutic dosage of carbamazepine (Simpson, 1966) and the relationship of therapy to the serological findings in our patient is not clear. However, before the overdose, our patient had taken very few carbamazepine tablets.

We conclude that this patient had subepidermal bullous formation occurring as a result of carbamazepine overdosage, the clinical pattern resembling a barbiturate-induced bullous eruption. Carbamazepine should be considered in the differential diagnosis of drug-induced coma with associated bullous lesions.

Acknowledgment

We thank Dr John Burton, Consultant Physician, for permission to publish the details of this patient under his care.
