Departments of Medicine and Pathology, University Hospital, University of the West Indies, Kingston, Jamaica, W. Indies.

Summary: Fifty three patients with drug-induced acute liver disease are reported. There were 35 females and 18 males with a mean age of 41 years. All but one patient had jaundice or hyperbilirubinaemia and 51 had abnormal liver enzymes. Histologically 38 patients (72%) had cholestatic injury while 15 had cytotoxic parenchymal damage. Methyldopa, chlorpropamide, chlorpromazine, halothane and the contraceptive pill accounted for 60% of cases. Fifty one patients recovered after drug withdrawal while 2 died of hepatic failure. Drug-induced liver injury must be considered in patients presenting with evidence of hepatic disease as the majority will recover on withdrawal.

Introduction

Drug-induced liver disease is a common clinical problem. Up to 25% of cases of fulminant hepatic failure may be the result of adverse reactions to drugs.1,2 For certain drugs such as isoniazid, chlorpromazine and methyldopa minor abnormalities in liver function tests can be detected in up to 20% of asymptomatic patients during therapy.3 These patients have minimal nonspecific focal hepatitis on liver biopsy often associated with both portal and intralobular inflammation. In addition it is estimated that approximately 2% of jaundiced patients admitted to general hospitals have drug-induced liver disease.4 In geriatric facilities the incidence may be 10-fold higher.1

The susceptibility of the liver to damage by drugs is a consequence of its primary role in drug metabolism.5 As the vast array of chemicals to which we are exposed expands and the number of implicated agents continue to increase, awareness of drug-induced liver disease is important in all areas of clinical medicine. Recognition of a drug aetiology is essential since the prognosis is generally good upon withdrawal.

We report on the clinical, aetiological and histological features of acute drug-induced liver disease seen at the University Hospital, Jamaica, over a 15 year period June 1973 to June 1988 were reviewed. The clinical presenting features, biochemical abnormalities, drug intake and outcome were studied. The histological details of all liver biopsy specimens were also reviewed. The histological classification used is modified from that proposed by Zimmerman and Ishak,6 for drug-induced hepatic injury. The biochemical abnormalities recorded were the initial or the highest value obtained.

Criteria for inclusion in the study were: (1) presence of jaundice and/or abnormal liver-related liver enzymes temporally related to (2) recent drug exposure, (3) absence of known previous underlying liver disease, (4) compatible hepatic histological findings and (5) improvement of abnormal clinical and biochemical parameters on withdrawal of the offending drug.

Patients with alcoholic liver disease, viral hepatitis, gall stones or evidence of extrahepatic biliary obstruction were excluded.

Results

There were 53 patients with drug-induced hepatic damage who satisfied at least four of the above criteria. The mean age at presentation was 41 years (median, 40 years; range 14–85). There were 35 females with a mean age of 40 years (range 14–85) and 18 males with a mean age of 41 years (range 15–73). The age distributions were: 0–9 years (0%); 10–19 years (13%); 20–29 (17%); 30–39 (19%); 40–49 (22%); and 50 years and older (29%).

The presenting clinical features are shown in Table I. All but one patient had jaundice or hyperbilirubinaemia (range 21–610 μmol/l). Twenty one patients (39%) had dark urine, and 8 (15%) had fever
and skin rash. The mean duration of symptoms was 35 days. Twenty patients (38%) had clinical evidence of hepatomegaly (1–9 cm below the right costal margin).

The liver-related enzymes (serum transaminase, alkaline phosphatase and gamma glutamyl transpeptidase) were abnormally elevated in the 51 patients in whom data was available. In 19 patients the abnormality was predominantly elevation of alkaline phosphatase (AP), gamma glutamyl transpeptidase (GGTP), and direct hyperbilirubinaemia. In 10 patients there was significant elevation of the transaminase with only minimal elevation of AP and GGTP. In 22 there was elevation of the transaminase, AP, GGTP and mixed hyperbilirubinaemia.

In 23% of patients there was elevation of the total leucocyte count (range 10.5–21.1 × 10⁹ cells/l). Five patients had absolute peripheral eosinophilia (>7/l).

Based on the predominant histological pattern, the types of liver damage are shown in Table II. Cholestatic hepatic injury was the commonest injury observed, occurring in 38 patients (72%). In 27 of these the changes were those of hepatocanicular cholestasis (cholestasis with portal tract inflammation) and in 11 canicular (bland) cholestasis was seen. Of the 15 cases with acute cytotoxic parenchymal injury, diffuse necrosis (as in viral hepatitis) was present in 10, while submassive or massive necrosis was the predominant change seen in 4. One patient had predominant steatosis.

Twenty two drugs were implicated in inducing liver injury (Table III). However, methyldopa (8), chlorpropamide (8), chlorpromazine (7), halothane (5) and the oral contraceptive pill (4) accounted for 60% of the cases. The type of injury produced was not predictable, but certain drugs were more often associated with a particular type of injury. Methyldopa was the causative agent in 8 patients. Of these hepatocanicular cholestasis was seen in 5, predominant diffuse necrosis was seen in two and submassive hepatocellular necrosis in the other patient. Chlorpropamide produced hepatocanicular cholestasis in 5 cases and diffuse necrosis in 3. Chlorpromazine produced hepatocanicular cholestasis in 6 and diffuse necrosis in 1. The oral contraceptive pill was associated only with canicular cholestatic injury, while halothane produced both cytotoxic and cholestatic damage.

Two patients died of hepatic failure. Both had massive hepatic necrosis induced by phenytoin and chlorpropamide respectively. The remaining 51 patients recovered clinically and biochemically after a mean interval of 63 days (range 9–168 days).

Discussion

Hepatic injury of many types may result from commonly used and generally well tolerated therapeutic agents. This has been demonstrated in our study, as a variety of therapeutic agents produced several types of hepatic injury. In our patients methyldopa, chlorpropamide, chlorpromazine, halothane and the oral contraceptive pill were the most commonly implicated drugs. Within the total number of patients with drug-induced liver injury there is an extremely variable frequency of injury from different drugs. However, only a minority of drugs known to cause abnormal hepatic function or jaundice account for the majority of reported cases. Apart from the contraceptive pill, which uniformly produced predominant cholestasis, the other drugs produced varying reactions.

The most frequently recognized drug-induced hepatic reactions are asymptomatic increases in the serum amino-transferases. Therefore the reported clinical cases probably represent only a fraction of all drug-induced liver injury. In addition, drugs can cause toxic effects on the liver which can mimic almost any naturally occurring acute or chronic hepatic disease in man. Occasionally therapeutic agents produce a symptomatic acute illness indistinguishable from viral hepatitis. Although absolute histological criteria of drug-induced injury have not been established, liver biopsy plays a vital role in diagnosis. Primarily, biopsy is

used to exclude the possibility of underlying chronic liver disease. In many instances chronic liver disease runs an insidious asymptomatic course similar to what is seen in some cases of drug-induced liver injury. However, in some cases jaundice may be the presenting feature and biopsy is the only reliable means of making an early diagnosis. When liver injury develops during treatment with an essential drug, liver biopsy plays an essential role in establishing a drug-induced injury or an unrelated disorder. Liver biopsy also provides information about the severity and prognosis in patients with drug-induced injury.

There are broad histological categories that relate to the morphology of drug-induced liver injury. Acute injury may be either cholestatic or cytotoxic, the latter manifesting virtually any of the morphological lesions known in hepatology. Diffuse massive or zonal necrosis may occur, accompanied by degeneration and steatosis. Cholestatic injury may be either canalicul (bland) or hepatocanalicular, when there is associated portal tract inflammation.

Accordingly, the whole spectrum of acute and chronic hepatocellular injury may be reproduced by drugs. Nevertheless, there are certain histological features which invariably point to drug-related injury. Linear or patchy, well defined necrosis, abundant eosinophils, large mononuclear phagocytes, bile duct injury, steatosis and non-caseating granulomas are frequent accompaniments to the general histological picture. However, there is significant overlap between these reactions and those produced by viral hepatitis and mechanical large duct biliary tract obstruction.

Final proof of an association between a drug and liver injury can only be established by epidemiological studies and rechallenge in an individual patient. However, in only a very few instances have patients been rechallenged with a drug. Death has been reported after rechallenge or when the drug was continued in the presence of symptoms. Rechallenge is therefore ethically unjustifiable. Consequently, validation of drug-induced hepatotoxicity depends on historical, clinical, biochemical and pathological data. In our patients there was no history of previous or underlying liver disease, the hepatic abnormality developed in temporal relationship to drug administration and in the majority complete clinical and biochemical recovery occurred on drug withdrawal.

Seventy two per cent of patients in this series had a predominant cholestatic reaction. This is in keeping with a compilation of adverse effects of drugs on the liver which revealed that cholestatic drug reactions were much more common than other manifestations such as hepatic necrosis. In our patients the biochemical results did not correlate with the histological pattern in some patients. This indicates the unreliability of routine serum liver related enzymes in indicating a specific histological pattern. The serum enzymes are indirect tests which are useful in the initial screening and as a crude guide to the possible hepatic pattern of injury. They may also serve as a transition to more specific diagnostic tests and as markers to be followed over long periods of time.

A number of factors affect susceptibility to drug-induced hepatic injury. However, the mechanisms by which susceptibility is increased are poorly understood. A female predominance of drug-induced injury is reported by several authors. Age may be another factor as drug-induced liver injury tends to occur in
older patients. In the present series, there was no patient under 9 years, and the number of patients increased with age, with the majority being women.

Drug reactions may be predictable (dose dependent) or unpredictable (dose independent). The majority of drug reactions fall into the latter category. The mechanism of drug-induced injury is uncertain but various mechanisms including hypersensitivity and genetic or acquired metabolic variation have been invoked. Certain drug reactions are accompanied by features that suggest the involvement of immunological mechanisms. These include fever, skin rashes, arthralgia, eosinophilia and autoantibodies. It is thought that in most instances, toxic drug metabolites or the immune responses to these metabolites mediate the damage. Selective impairment of certain vital cellular functions may result in lethal injury to hepatocytes, whereas selective impairment to the bile secretory apparatus may result in cholestasis.

In conclusion, the physician must consider a drug-related aetiology in patients presenting with evidence of hepatic disease whatever the clinical picture. This is especially important in middle aged or elderly patients. In such situations it is imperative to obtain a detailed and accurate drug history as discontinuation of the offending drug will lead to improvement in the majority.
