Missed Diagnosis

Neuromuscular disease, respiratory failure and cor pulmonale

Summary: Respiratory muscle weakness is an uncommon cause of chronic respiratory failure and a rare cause of cor pulmonale. The problem may not be apparent unless specific physical signs are sought or appropriate investigations performed. We present three patients who presented diagnostic difficulty for prolonged periods until the presence of respiratory muscle weakness was considered. Once the diagnosis was established treatment with nocturnal nasal intermittent positive pressure ventilation produced a dramatic improvement in symptoms and allowed a return to a near normal lifestyle.

Introduction

Muscle weakness is rarely considered when a cause of chronic respiratory failure and/or right heart failure is being sought. We report three patients who presented diagnostic difficulty for considerable periods until this possibility was considered.

Case reports

Case 1

A 35 year old woman was referred for investigation of respiratory failure. She had always been of short stature and low weight and as a child was never good at sports. She had attended an open-air school because of recurrent chest infections. She had been breathless on exertion for many years.

Following her second pregnancy at age 32 she had had persistent left basal pneumonia and subsequent recurrent respiratory infections. A presumptive diagnosis of bronchiectasis was made; cystic fibrosis was considered and was excluded by a normal sweat test. Finally she was admitted to hospital following a respiratory arrest at home associated with a chest infection. This necessitated prolonged assisted ventilation, latterly via tracheostomy with subsequent slow recovery and eventual weaning from the ventilator.

She was then transferred to our department for further investigation. Further questioning revealed symptoms of morning headache and 'muzziness' present for several months. On examination she was thin and wasted; she was able to lie supine without discomfort and with no abdominal wall paradox but she had an audibly weak cough. There was a generalized reduction in muscle bulk and power with no fasciculation or myotonia. Respiratory function tests (Table I) showed severe respiratory muscle weakness with hypercapnia but only mild daytime hypoxaemia. Overnight oximeter recording of oxygen saturation (SaO2) however showed profound desaturation, with values during most of the night below 80% and a nadir of 50%. Polysomnography demonstrated hypventilation but no periods of apnoea.

A diagnosis was made of congenital myopathy, with profound respiratory muscle weakness and respiratory failure. This was supported by an elevated serum creatine kinase, a characteristic electromyogram and muscle biopsy which showed a marked myopathic process without specific features. She was treated with nocturnal intermittent positive pressure ventilation, initially via the tracheostomy and subsequently by nasal mask. On this treatment there was a gratifying improvement in symptoms over a number of days and repeat overnight recording of SaO2 showed values for most of the night greater than 90% with a nadir of 80% (Table I). She is now back to leading an active life, looking after her family with little restriction in activity.

Case 2

A 27 year old woman presented with malaise, breathlessness and ankle swelling of 2 weeks' duration. On examination there were signs of right ventricular failure. She gave a history of frequent chest infections and recurrent left lower lobe collapse from the age of one year. A chest radiograph at the age of 12 had been said to show right ventricular enlargement. She had always been weak, underweight and unable to participate in sports and she had difficulty walking upstairs. No organic cause had been found and the diagnosis of anorexia nervosa had been suggested.

At presentation the chest radiograph showed cardiomegaly, bilateral pleural effusions and engorgement of the pulmonary veins. The electrocardiogram showed right ventricular hypertrophy with right axis deviation and an echocardiogram showed right ventricular dilatation; the left ventricle did not appear distended but its function was impaired. The fluid retention was treated with diuretics and she was referred for investigation of a presumed cardiomyopathy. These findings together with the patient's generalized weakness suggested the presence of a congenital myopathy which on muscle biopsy was shown to be nemaline disease.

Respiratory function showed a very severe restrictive ventilatory defect and hypercapnic respiratory failure. Overnight recording of SaO₂ confirmed profound desaturation despite breathing supplemental oxygen (Table I). She was treated with nasal positive pressure ventilation (NPPV) at night and for a few hours each afternoon with improvement in her symptoms, physical signs and daytime blood gases (Table I) over a period of a week. Since then she has become more active than ever before, leading an essentially normal life, and her weight has increased from 32 to 51 kg.

Case 3

A 36 year old man was admitted to hospital with a 10 day history of mild breathlessness and ankle swelling. He had previously been well and able to run his own business, and had not previously consulted a doctor. He was a non-smoker. On examination he was obese and cyanosed, with grossly elevated venous pressure, a loud pulmonary component of the second sound, a fourth heart sound, marked oedema and ascites. Investigation showed polycythaemia, right ventricular hypertrophy on electrocardiogram and hypercapnic respiratory failure. Overnight oximetry showed severe hypoxaemia. He was treated with venesection, oxygen and diuretics with improvement in the signs
and symptoms, and he was transferred to our unit with a presumptive diagnosis of obstructive sleep apnoea syndrome.

Further enquiry revealed a family history in his younger brother of multiple operations for club foot and his mother had bilateral hand weakness and wasting with a 'steppage' gait. Examination of the patient in the supine posture showed paradoxical motion of the anterior abdominal wall on inspiration. Neurological examination demonstrated slight wasting of the thenar eminence with normal power in the upper limbs, the triceps jerk was just present but the other reflexes were absent, power of ankle flexion was poor and eversion was absent. Sensation was altered up to mid-calf and he demonstrated a 'steppage' gait. A diagnosis was made of hereditary motor-sensory neuropathy Type 1 (Charcot-Marie-Tooth disease) with diaphragmatic weakness, and this was confirmed by further investigation. Echocardiography showed a thickened but well-functioning right ventricle. Nerve conduction velocity studies showed a combined demyelinating/axonal neuropathy with evidence of marked conduction block in some of the nerves, a feature regularly seen in primary demyelinating disorders; this was in keeping with the putative diagnosis and the findings were similar to those found in his relatives. Respiratory function tests (Table 1) showed a severe restrictive ventilatory defect with a marked postural fall in vital capacity, poor maximal inspiratory pressure measured at the mouth and a very low transdiaphragmatic pressure (Pdi) during a maximal sniff, confirming severe bilateral diaphragmatic weakness. Polysomnography showed severe hypoventilation without apnoea (Table 1).

He was treated with nocturnal NPPV with symptomatic improvement and resolution of clinical signs and was able to return to work within 2 months.

Discussion

Respiratory failure in patients with neuromuscular disease results from hypoventilation consequent on impaired respiratory muscle function and reduced lung compliance. In each of the three patients described here, weakness had been present for at least 20 years but because of its very slow progression it had gone unrecognized. Each had caused considerable diagnostic difficulty and in two the major respiratory problems came to light only with the development of cor pulmonale.

Unlike the situation with scoliosis, the development of 'right heart failure' seems to be an unusual manifestation of respiratory failure due to respiratory muscle weakness. Both congenital myopathy and hereditary motor-sensory neuro-

pathy are recognized, albeit rare, causes of respiratory muscle weakness. Diagnostic difficulty in the patients described here probably arose for several reasons. The congenital myopathies usually present in childhood or adolescence, so the condition is less likely to be diagnosed in adults. In the case of hereditary motor-sensory neuropathy diaphragmatic weakness is known to occur but it is rarely sufficient to cause symptoms or the development of respiratory failure.

In the absence of a positive family history, consanguinity, or obvious clinical features of neuromuscular dysfunction, slowly progressive muscle weakness often causes diagnostic difficulty. Suggestive features include recurrent chest infections in childhood and inability to participate in games. Breathlessness on exertion may not be a prominent feature as many patients are unable to exercise sufficiently to become breathless. Occasional patients present with difficulty in weaning from a ventilator after a routine surgical procedure, or with morning headache and daytime somnolence associated with nocturnal hypoventilation. Examination may reveal selective muscle wasting and weakness although most of these patients have 'slim limbs'. Other signs of neuromuscular dysfunction, particularly fasciculation and myotonia, should always be sought.

Investigation can provide clues to the diagnosis with, for instance, a chest radiograph reported as showing 'poor inspiratory effort' because of elevation of the diaphragm. The diagnosis of respiratory muscle weakness is confirmed by the finding of a restrictive ventilatory defect and a marked impairment of maximal respiratory pressures. A marked postural fall in vital capacity (> 25%) is related more specifically to weakness or paralysis of the diaphragm. Electrophysiological studies and muscle biopsy provide definitive diagnostic information.

Treatment depends on the underlying cause and prognosis. Nocturnal ventilatory support, with either positive or negative pressure has become established as effective therapy in appropriate cases and its beneficial effects are well recognized. As well as improving nocturnal pulmonary gas exchange, its use also leads to increased PaO2 and reduced PaCO2 by day when the patient is breathing spontaneously. Nasal positive ventilation is a recent modification of this technique utilizing a well-fitting nasal mask. It is generally well tolerated and has become the method of choice for patients such as those described. There is little impairment in communication as the mask is generally worn only whilst the subject is sleeping. Providing patients are able to move their hands to their face the non-invasiveness, simplicity and semi-portability of the equipment makes it the most acceptable technique in most circumstances.
In conclusion, chronic respiratory muscle weakness may be difficult to recognize and should be considered in any patient with cardio-respiratory failure in whom the cause is not immediately apparent.
