An unusual but important cause of sciatica

SKC Toh, S Ellis, V Bahal

An 85-year-old man presented to the rheumatologist with a three-year history of increasingly severe lower back pain, radiating down both his legs, with reduced straight-leg raising and a positive sciatic-nerve stretch test. He had no urinary or bowel symptoms, and abdominal examination was unremarkable. As part of his management, he had an epidural with a local anaesthetic, resulting in acute urinary retention. Rectal examination performed after catheterisation revealed a 'pulsatile' prostate. Ultrasound scan (figure 1) and computed tomography (CT) (figure 2) of the pelvis were then obtained.

Questions

1. What is the diagnosis?
2. How may this condition present?
3. What further investigations and management may be advised?
Answers

QUESTION 1
Multiple iliac aneurysms. Careful abdominal, rectal and vaginal examination may lead to the diagnosis in 70% of cases. The ultrasound scan demonstrated one of these aneurysms. CT scan showed bilateral internal iliac aneurysms (9 x 8 cm right and 5 x 6 cm left).

QUESTION 2
Iliac aneurysms represent less than 2% of intra-abdominal aneurysms, although the incidence is increasing with the advanced longevity of the population and with improved detection. They are often associated with aortic aneurysms, and are rarely isolated. Even when confined to the iliac vessels, 70% are multiple rather than solitary aneurysms.

Up to 45% may be asymptomatic until they rupture. In these patients, clinical suspicion should be roused in any patient with risk factors for atherosclerotic disease or the presence of aneurysmal disease elsewhere (this patient, in fact, had a known anterior communicating artery aneurysm). In patients having ultrasound screening for aortic aneurysms, attempts have been made to examine the iliac vessels, although because of bowel gas, obesity and vessel tortuosity, this can sometimes be difficult.

Due to the limited number of cases and series reported, no correlation of size and site with risk of rupture has been made, although the risk of rupture appears high and apparently unrelated to aneurysm size. Nevertheless, the evidence so far has led some authors to recommend repair of any iliac aneurysm greater than 3 cm in diameter. All these patients should be considered for surgery as elective surgery carries a significantly better operative mortality (7–11%) than emergency repair of rupture (20–57%).

About 70% of patients present acutely with a leaking or ruptured aneurysm. Some patients may present with compression and erosion of surrounding structures including the bowel, bladder, ureters, pelvic veins and nerve roots resulting in vascular-enteric fistulae, haematuria, renal colic, arteriovenous fistulae and sciatic pain, respectively. In particular, nerve root compression may be chronic or acute, the latter suggesting impending or actual leak requiring urgent surgery.

This patient illustrates well the elusive nature of this condition. Careful rectal examination was the key to diagnosis.

QUESTION 3
The patient was increasingly debilitated by his symptoms and was keen to have further treatment. As he was slender and remarkably fit for his age, he was referred for surgical assessment. It is important to emphasise that surgery in this age group is not without increased risks but the patient was aware of this and remained adamant that he wished to proceed. If the patient had had little or no symptoms, it may have been justifiable to perform serial ultrasound scans of his iliac vessels and contemplate surgery only if there were increases in size of the aneurysms. Digital subtraction arteriography was performed to defined the aneurysms which appeared to be confined to the iliac vessels (figure 3). At operation, he was found to have aneurysmal common and internal iliac vessels (figure 4).

The common iliac aneurysms were ligated and replaced with a bifurcation Dacron aorto-iliac graft. There was found to be good backflow distal to the internal iliac aneurysms which were safely ligated, the anterior walls excised and obliterator endoaneurysmorrhaphy performed. The surgical points to note are that distal control is vital to achieve safe control of internal iliac aneurysms and that the presence of good backflow meant that isolation of both internal iliac arteries can be safely done without risk of colonic or perineal ischaemia.

The patient made a good recovery with relief of his symptoms and remained well one year on.

Final diagnosis

Multiple iliac aneurysms.

Keywords: iliac aneurysm, sciatica

Breathlessness in an Afro-Caribbean woman

HRS Roberts, DM Hansell, R Wilson, PJ Cole, CRK Hind

A 32-year-old Afro-Caribbean woman presented with a two-month history of weight loss and pleuritic chest pain, and a two-week history of night sweats, and cough productive of blood-stained green sputum. She had no previous respiratory history of note, was not aware of having had tuberculosis, had no haemoglobinopathy, and denied exposure to risk factors for HIV infection. Examination was unremarkable apart from signs of left upper lobe consolidation, which was confirmed by chest radiograph. Sputum microscopy revealed acid-alcohol fast bacilli. Anti-tuberculous therapy (rifampacin, isoniazid, and ethambutol with pyridoxine) was started.

Despite the treatment she became increasingly breathless over the next few days, until she was dyspnoeic at rest. She refused an HIV test. Examination one week after the start of therapy revealed: no pyrexia, a pulse of 100 beats/minute and regular, blood pressure 120/80 mmHg (no postural drop), no murmurs, a respiratory rate of 28 per minute, and features of left upper lobe consolidation/collapse. Investigations showed: haemoglobin 9.6 g/dl, white cell count 14.1 $\times$ 10$^9$/l, platelets 374 $\times$ 10$^9$/l, normal serum urea and electrolytes; arterial blood gases: pH 7.43 (7.42), PaCO$_2$ 3.99 kPa (3.78), PaO$_2$ 9.80 kPa (22), bicarbonate 23 mmol/l (22), oxygen saturation 85% (96%) while breathing room air (figures in brackets while breathing 60% oxygen); electrocardiogram was normal; the collapse/consolidation of the left upper lobe was unchanged on chest X-ray. Prednisolone 60 mg daily was added to the treatment.

Over the next 48 hours her breathlessness continued to increase, and her tachycardia increased to 130 beats/minute, but the findings on examination were otherwise unchanged. An arterial sample acquired while the inspired oxygen fraction was 60% showed: pH 7.52, PaCO$_2$ 4.02 kPa, PaO$_2$ 7.13 kPa, bicarbonate 24 mmol/l. A chest X-ray was performed (figure 1).

Questions

1 What is the likely explanation for the patient’s increasing breathlessness?
2 Which imaging techniques might you use to reach the correct diagnosis?
An unusual but important cause of sciatica.
