Abnormal movements associated with severe hyponatraemia

Nages Nagaratnam, Evelyn Icao, Helen Peric

Summary
An elderly woman with severe hyponatraemia manifested transient choreoathetoid movements of the upper extremities and dyskinetic movements of the face and mouth. She showed more than one type of hyponatraemia and a precise diagnosis was not possible. The movements were abolished with treatment of the hyponatraemia with no recurrence or sequelae.

Keywords: hyponatraemia, diuretic, abnormal movements

Hyponatraemia (serum sodium level <130 mmol/l) is the most common electrolyte abnormality, especially in the elderly, and occurs with a wide variety of medical conditions. Asymptomatic hyponatraemia often goes undetected and with severe hyponatraemia the clinical presentation can be diverse and non-specific such that early recognition can be delayed.1 A wide variety of neurological manifestations has been associated with hyponatraemia and severe hyponatraemia can have damaging effects on the central nervous system.2 Generalised disturbances such as inappropriate behaviour, hallucinations (both visual and auditory), unresponsiveness, seizures, and coma are the more frequent manifestations.3 We describe an elderly woman with severe hyponatraemia with choreo-athetoid and dyskinetic movements.

Case report
A 77-year-old woman presented with intermittent dizziness and vomiting for over three months which had worsened over the past week. She was said to have Ménière's disease and had been on nicotinic acid, a combined diuretic (amiloride and hydrochlorothiazide) and prochlorperazine (5 mg tid) for several weeks. The subsequent diagnosis was benign paroxysmal positional vertigo. The medical history was of no clinical significance, but for diet-controlled diabetes. She had never been on neuroleptics and is a non-drinker and a non-smoker.

On admission the vital signs were unremarkable. The cardiovascular, respiratory and central nervous system were normal. The serum sodium was 134 mmol/l, potassium 3.1 mmol/l, blood glucose 11.1 mmol/l, calcium 2.37 mmol/l, magnesium 0.62 mmol/l, urea 5.8 mmol/l and creatinine 6.5 μmol/l. Computed tomography (CT) scan of the brain was normal. She remained on the diuretic and prochlorperazine. Four days following admission vomiting worsened and three days later she was found groaning at 08.00 h. She was conscious, but did not respond to verbal commands. She had mouthing movements involving the face, mouth and tongue, simulating tardive dyskinesia and writhing with sudden jerky movements of the upper limbs. The lower limbs were in extension with slight increase in tone. The pupils were equal and reactive. The plantars were flexor. There were no abnormalities in the other systems. The chest X-ray was normal. Routine haematology and liver function tests were normal. Her medications were stopped.

By 11.00 h her level of consciousness had worsened. She was unresponsive, but the movements continued and the plantars were extensor. The serum sodium level was found to be 101 mmol/l, potassium 3.7 mmol/l, urea 6.2 mmol/l, creatine 68 μmol/l, plasma osmolality 217 (275–295) mosm/kg, glucose 12.2 mmol/l, cholesterol 4.5 mmol/l, triglycerides 2.8 (0.1–1.85) mmol/l, sodium 117 mmol/l, potassium 6.1 mmol/l, urine osmolality 478 (300–600) mosm/kg. CT scan of the brain revealed no abnormality. She was commenced on normal saline. She had a generalised seizure, but was not given anticonvulsants. At 20.00 h she was still unconscious, the plantars were flexor and no movements were seen. Her serum sodium was 112 mmol/l. She was then given 3%...
sodium chloride 500 ml over 10 h and by 24.00 h the sodium was 116 mmol/l, potassium 3.7 mmol/l.

On day 2, her level of consciousness had improved. The serum sodium was 118 mmol/l, potassium 2.6 mmol/l and magnesium 0.58 mmol/l. The last two were included in the infusion. Normal saline was then commenced, a litre 8-hourly. After 48 h, serum sodium was 124 mmol/l, potassium 3.4 mmol/l and magnesium 1.09 mmol/l. On day 3, she opened her eyes spontaneously and responded to verbal commands. There were no focal or lateralising neurological signs. Thereafter her condition improved and remained stable and on day 7 her sodium was 136 mmol/l and potassium 4 mmol/l; she was mobilising independently and was discharged home on day 11. Blood sugar levels from days 1 to 11 ranged from 3.0–12.2 mmol/l with no treatment. She was pre-
scribed prochlorperazine (Stemetil) with no recurrence of symptoms. When reviewed six weeks later there was no overt abnormality and prochlorperazine was stopped. On further follow-up over 18 months she remained well and her blood sugar was 5.5 mmol/l.

Discussion

Our patient had severe hyponatraemia (serum sodium 101 mmol/l) with abnormal move-
ments. She responded to sodium replacement with a correction of 24 mmol/l in the first 48 h. She recovered without any recurrence or sequelae. She had been on a combined diuretic until the onset of the abnormal movements.

More than one type of hyponatraemia could have contributed to her clinical state. The biochemical findings at the onset were that of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). SIADH is common in the elderly and has many causes (eg, infection/malignancy), although there was no obvious cause in our patient other than for the thiazide therapy. There are, however, other mechanisms which may have contributed in some degree to the hyponatraemia. Namely (a) the intractable vomiting and diuretic, (b) hyperglycaemia, and possibly (c) pseudohypona-
traemia due to mildly elevated triglycerides.

It had been suggested that rapid correction of the hyponatraemia could lead to central pontine myelinolysis. It is now accepted that central pontine myelinolysis is almost never seen with hyponatraemia and is associated with medical conditions such as alcoholism, sepsis, advanced liver disease or malignancies.3 In hyponatraemia the observed lesions were diffuse areas of cerebral infarction. The rate of correction is said not to be a factor in the genesis of hyponatramic brain injury but the absolute increase should be within 25 mmol/l in the first 48 h of treatment.4 Brain damage often occurs in untreated patients with hypo-
