Self-assessment questions

An unusual rash

Paul F Findlay, W R Primrose

A 74-year-old man with a history of rheumatoid disease, and a left lower lobectomy for carcinoma of lung 25 years previously was admitted as an emergency to hospital with a 3-day history of a purpuric rash. The rash was noted initially on the feet and spread proximally to involve the thighs and buttocks with involvement of the extensor surface of the upper limbs but sparing of the trunk. There were no other symptoms apart from mild colicky abdominal pain and a minor sore throat before the onset of the rash. His rheumatoid disease was quiescent at the time and there had been no recent changes in his drug therapy.

Examination confirmed the presence of a purpuric rash (figures 1 and 2) in the absence of systemic illness. Routine blood testing was normal aside from a slightly elevated urea at 7.6 mmol/l with a normal creatinine. A clotting screen was also within normal limits. The erythrocyte sedimentation rate was 26 mm/h and a mid-stream urinalysis revealed microscopic haematuria with 1 + red blood cells and no growth. During his period of hospitalisation he passed a melaena stool on one occasion but there was no haemodynamic compromise and all parameters remained normal.

Questions

1. What is the probable diagnosis?
2. What complications can occur?
Answers

QUESTION 1
Henoch-Schönlein purpura (HSP). This is an inflammatory disorder of blood vessels characterised by non-thrombocytopenic purpura, commonly distributed over the buttocks and lower extremities, arthralgia, abdominal pain and a form of glomerular nephritis. It is mediated by immune complex deposition, predominantly IgA, which affects the small blood vessels resulting in a local vasculitis. Histologically the predominant cell type is the polymorphonuclear leucocyte.

QUESTION 2
Complete recovery from this condition is the rule, but complications can occur (box).

Complications of Henoch-Schönlein purpura
- renal failure
- abdominal pain, peritonitis, bowel perforation, gastrointestinal blood loss
- pulmonary haemorrhage

Discussion
Henoch-Schönlein purpura preferentially affects children between the ages of 5 and 15 years with a slight bias towards the male gender (M:F = 1.5:1). In this population, which has been extensively studied, the condition is deemed to be benign and self-limiting with few complications. This disorder can, however, be expressed in adult life and until recently received little attention. A comparison of HSP in children and adults revealed that differences do exist between the two population groups. Cutaneous lesions were found to be the main clinical manifestation in both groups and in the adult population joint symptoms were predominant over abdominal pain in comparison with the paediatric group. Similarly, adults were preferentially subject to more renal involvement than children and often required immunosuppressive treatment. Interestingly, with regard to this particular case, preceding upper respiratory tract infection was a more frequent feature amongst children.

Case reports have appeared in the literature underlining the potential for serious sequelae of HSP in adults with nephritis, pulmonary haemorrhage, and bowel perforation being reported. There is also evidence for HSP as a cutaneous marker for underlying malignancy. An association with leukaemias and lymphomas, although rare, is recognised and one case report quotes the expression of HSP in tandem with the progression of a malignant breast tumour. Despite the different expression between the paediatric and adult forms, the final outcome in both groups is equally good.

Final diagnosis
Henoch-Schönlein purpura.

Keywords: vasculitis; Henoch-Schönlein purpura

Large subcutaneous nodules in lower limbs following thyroiditis

Atul Kakar, S P Byotra

A 20-year-old woman was admitted with complaints of fever and polyarthralgia since January 1996. All investigations including collagen markers were negative. The patient was treated with analgesics and showed improvement. In July she noticed a thyroid swelling with low-grade fever, and investigations showed that she was hypothyroid. Antimicrosomal antibodies were positive and antithyroglobulin was negative. Thyroid receptor antibody status was not available. Thyroid fine needle biopsy showed chronic lymphocytic thyroiditis. She was put on thyroid hormone replacement therapy.

In February 1997 she noticed multiple subcutaneous lumps in the lower limbs. She also complained of low-grade fever and arthralgia. There was no malar or discoid rash or rash elsewhere on the body. On examination, the lumps were hard, mobile, and non-tender, varying in size from 3–7 cm. She was febrile and had swelling of the small joints of both hands. Investigations showed normal blood picture, erythrocyte sedimentation rate was 130 mm in 1st hour, ANA and dsDNA both were strongly positive. Anti-Sm, and antiphospholipid antibodies (IgG, IgM) were negative. Lupus anticoagulant was positive. Echocardiography showed mild pericardial effusion. Chest X-ray was normal and X-ray of the hands did not show any erosion. Liver, renal function tests, serum calcium, phosphorus, alkaline phosphatase, parathyroid levels, creatine phosphokinase, barium swallow and pulmonary functions test were all normal. Rheumatoid factor was negative. X-Rays of the lower limbs are shown in figures 1 and 2.

Questions

1. What are the X-ray findings?
2. What is the diagnosis?

Figure 1 X-Ray of the lower limbs

Figure 2 X-Ray of the lower limbs
Answers

QUESTION 1
Extensive calcification in subcutaneous tissue of lower limbs.

QUESTION 2
Calcinosis cutis in systemic lupus erythematosus (SLE). The patient fulfilled the criteria of the American Rheumatism Association for the diagnosis of SLE. Fine needle biopsy from the nodules showed calcium deposits in subcutaneous tissues and was consistent with the diagnosis of calcinosis cutis.

Discussion

Calcium deposits in the skin can occur in connective tissue disorders such as dermatomyositis and scleroderma. Although calcinosis cutis in such collagen disorders is not rare, its occurrence in cases of SLE is, and only 30 cases have been reported. Calcinosis cutis is extremely rare in mixed connective tissue disorders. Although it is common in scleroderma, it is rare in morphea and was reported in only one of 74 patients by Muller.1 The clinical examination of our patient was not suggestive of such a disorder.

Calcinosis cutis may be an incidental finding or may present as subcutaneous tumours. The calcinosis may involve a small area (circumscripta) or be diffuse (universalis). In dermatomyositis, the calcium deposits occur in shoulders and hips of young men. The deposits are usually large, in contrast to scleroderma in which they are small and occur in fingers of adults. All the above conditions are examples of dystrophic calcification and the product of serum calcium and phosphorus levels is not raised. The exact mechanism of calcification in SLE is not known. The proposed mechanism involves trauma and inflammation, which denature the protein in necrotic tissue. The phosphates bind to denatured protein and act as a nidus for calcification. The other mechanism involves the increased activity of alkaline phosphatase in the local tissue by lysosomes leading to calcification. Although intravenous steroids, aluminum hydroxide, and etidronate have been shown to be useful, medical treatment is usually not successful. Surgical excision of the lesion with skin grafting has been recently shown to be beneficial.1 Our patient was unusual as she had calcinosis cutis associated with relatively mild SLE which was of shorter duration.

Our patient also had thyroid involvement, the prevalence of which is 7.5% in cases of SLE.2 This prevalence is greater than that seen in the general population. In SLE, thyroid function tests are frequently abnormal and thyroid autoantibodies may be present without disease being actually present. Thyroid disease in SLE occurs before the diagnosis of SLE is made or after stopping the immunosuppressive therapy.

Final diagnosis

Thyroiditis with calcinosis cutis universalis in SLE.

Keywords: thyroiditis; calcinosis cutis; systemic lupus erythematosus

Calcinosis cutis in SLE

- rare cause of calcinosis cutis
- product of calcium and phosphorus is normal
- common site of calcinosis is lower limb
- may be associated with myopathy
- occurs with long-standing, severe disease
- calcification may be bilateral and diffuse or unilateral and localised

Box 1

Thyroid disorders in SLE

- diagnosis may be missed because of overlap of non-specific symptoms
- patients with autoimmune thyroiditis may develop SLE
- HLA- B8 DR3 occur more commonly with SLE and autoimmune thyroiditis
- both hyper- and hypothyroidism occur in SLE
- SLE patients on steroids, nonsteroidal anti-inflammatory agents, beta-blockers and dilantin would have lower T3 and T4 values while propylthiouracil used to treat thyrotoxicosis rarely causes SLE

Box 2

Dermopathy in primary hypothyroidism or chronic lymphocytic thyroiditis is exceptionally rare.6 In 15–20% patients with Graves’ disease, there is dermopathy over the dorsal surface of the legs or feet called pretibial myxoedema.6 This commonly presents with ophthalmopathy and is a late manifestation of Graves’ disease. Older patients are more at risk for developing this dermopathy.7 The affected area is raised, circumscribed and thickened. It has a peau d’orange-like appearance. There is a localised area of hyperpigmented and non-pitting oedema. The lesions may rarely be plaque, nodular or polypoidal. Histologically there is lymphocyte infiltration and metachromatic material is seen in the deeper layers of the dermis.8

In calcinosis cutis the lesions may be diffuse and bilateral and commonly occur in lower limbs.1 The calcification occurs in a diffuse, linear, streaky or nodular form. Calcifications may also be plaque-like along the anterior aspect of lower limbs; they are hard on palpation. There may be associated myopathy, peripheral vascular calcification, or skin ulcerations. The skin biopsy in these patients may show extensive deposition of collagen in dermal and subcutaneous tissue with calcification.
Gestational pancreatitis complicating uncontrolled diabetes mellitus

Shih-Yi Lin, Ya-Yu Wang, Shing-Win Shiao, Hong-Da Lin, Shih-Tzer Tsai

A 36-year-old G, P, AB, woman was admitted to our hospital due to nausea, vomiting and severe epigastric pain for one day at 24 weeks gestation. She had a history of diabetes for one year, but was not receiving any medical treatment. The patient also denied any other drug history or alcohol drinking. Physical examination revealed a blood pressure of 150/100 mmHg, body temperature 37°C, weight 60 kg, and height 159 cm. Cutaneous eruptions or xanthomas were not seen. The epigastric tenderness was severe, but without rebounding pain or muscle rigidity. Pelvic examination was unremarkable. Fundus height was 22 cm and foetal heart rate 140 beats/min. Laboratory studies showed a serum amylase level of 457 U/l (normal range <180 U/l) and lipase 1056 U/l (<190 U/l). Plasma sugar was 12.9 mmol/l, triglycerides 81.8 mmol/l and total cholesterol 20.7 mmol/l. Hba1c was 10.2% (4–6%), and postprandial serum C-peptide 0.2 nmol/l. Arterial blood gasses were pH 7.23, pO2 113 mmHg at room air, pCO2 21 mmHg, base deficit 15 mmol/l. Blood ketone reaction was strong with 1:4 dilution. Abdominal sonography disclosed a swelling pancreas, but no evident biliary tract disease. Under a provisional diagnosis of acute pancreatitis, parenteral dextrose (2000 kcal/day by 50% glucose water and 0.9% glucose saline) and intravenous insulin were administered. Ketoacidosis was promptly corrected in one day and serum triglyceride was decreased to 13.5 mol/l by the seventh day. Thereafter a low fat diet was resumed and plasma sugar was well controlled by daily subcutaneous insulin. The serum triglyceride was further lowered to 3.3 mol/l after 2 weeks. The patient had a weight gain of 3 kg within 3 weeks of hospitalisation and finally gave birth to a healthy baby of 2600 g by caesarean section at the 38th week of pregnancy.

Questions

1. What is the most likely cause of acute pancreatitis in this pregnant woman?
2. What are the possible mechanisms of her extreme gestational hypertriglyceridaemia?
3. How should her hypertriglyceridaemia be managed?
Answers

QUESTION 1
Gestational pancreatitis is a rare complication with a high mortality for mother and foetus, the most common cause being biliary tract disease. However, in women with an underlying disorder of lipid metabolism, the possibility of gestational hypertriglyceridaemic pancreatitis should never be overlooked. Pregnancy is often associated with increased plasma VLDL-TG levels and a marked hypertriglyceridaemia, over 2000 mg/dl, may even occur in some patients. Recently, some authors have stated that oestrogen therapy in diabetic women may lead to an extreme hypertriglyceridaemia, particularly in an uncontrolled galactacemic state, and then possibly induce acute pancreatitis. However, gestational hypertriglyceridaemic pancreatitis complicating uncontrolled diabetes has rarely been reported.

It had been shown that diabetic pregnancies are associated with higher plasma triglycerides than normal ones. Moreover, the increased levels of plasma triglycerides has been shown to be related to diabetic control. The accentuated hypertriglyceridaemia may be produced by a synergistic effect of diabetes and pregnancy on VLDL synthesis. In our patient, who had an uncontrolled diabetes before pregnancy, this is the most probable explanation for her extreme hypertriglyceridaemia. Nevertheless, we did not perform any other investigation of genetic lipid abnormalities on our patient or her family and could not exclude the possibility of an endogenous lipid disorder, in spite of the good recovery of hypertriglyceridaemia after insulin infusion. Diabetic ketoadidosis, another acute metabolic complication noted in our patient, could also be associated with hypertriglyceridaemia.

Learning points

- pre-existing hypertriglyceridaemia may be exacerbated by pregnancy and thus induce a risk of acute hypertriglyceridaemic pancreatitis
- uncontrolled diabetes may exacerbate gestational hypertriglyceridaemia
- strict glycaemic control is effective in managing gestational diabetic hypertriglyceridaemia

However, in the reported cases, hypertriglyceridaemia over 7000 mg/dl has rarely been found and our patient’s hypertriglyceridaemia could not be attributed to diabetic ketoadidosis alone.

QUESTION 2
Diabetes is known as a common cause of secondary lipid metabolism disorder and is often associated with increased plasma VLDL-TG levels and a marked hypertriglyceridaemia over 2000 mg/dl, may even occur in some patients. Recently, some authors have stated that oestrogen therapy in diabetic women may lead to an extreme hypertriglyceridaemia, particularly in an uncontrolled galactacemic state, and then possibly induce acute pancreatitis. However, gestational hypertriglyceridaemic pancreatitis complicating uncontrolled diabetes has rarely been reported.

It had been shown that diabetic pregnancies are associated with higher plasma triglycerides than normal ones. Moreover, the increased levels of plasma triglycerides has been shown to be related to diabetic control. The accentuated hypertriglyceridaemia may be produced by a synergistic effect of diabetes and pregnancy on VLDL synthesis. In our patient, who had an uncontrolled diabetes before pregnancy, this is the most probable explanation for her extreme hypertriglyceridaemia. Nevertheless, we did not perform any other investigation of genetic lipid abnormalities on our patient or her family and could not exclude the possibility of an endogenous lipid disorder, in spite of the good recovery of hypertriglyceridaemia after insulin infusion. Diabetic ketoadidosis, another acute metabolic complication noted in our patient, could also be associated with hypertriglyceridaemia.

Conclusion
A moderate hypertriglyceridaemia due to uncontrolled diabetes may have existed in our patient before pregnancy and was markedly exacerbated by the gestation. In consequence, acute hypertriglyceridaemic pancreatitis occurred, complicated by diabetic ketoadidosis. Pancreatitis is a rare but serious event during pregnancy. Pregnant women with inadequately controlled diabetes may be at risk of hypertriglyceridaemia. Strict diabetic control during pregnancy is warranted to prevent hypertriglyceridaemic pancreatitis and achieve an optimal outcome for mother and foetus.

Final diagnosis
Gestational hypertriglyceridaemic pancreatitis and diabetic ketoadidosis, due to uncontrolled diabetes mellitus.

Keywords: diabetes; hypertriglyceridaemia; pregnancy; pancreatitis

A young woman with fluctuating hypo- and hyperthyroidism

A Bhattacharyya, K G Chan, D J Tymms

A 30-year-old woman presented for the first time in August 1990 with signs and symptoms of hypothyroidism: weight gain, fatigue, and muscle aches. She had a small goitre, but no ophthalmopathy or dermopathy. She was a non-smoker and mother of two (last childbirth 2 years previously). There was no history of thyroid disease or drug consumption. Thyroid function tests confirmed the diagnosis of primary hypothyroidism: thyroid-stimulating hormone (TSH) 74 mU/l (reference range 0.4–5 mU/l), free thyroxine (FT4) 2.4 nmol/l (9–24). Thyroid microsomal antibody (TMA) and antithyroglobulin antibody were positive (one in 256 000 and 1600, respectively). Replacement therapy with thyroxine was started (100 µg daily). Over the next 6 months her dose requirement for thyroxine was reduced to 50 µg daily and the drug was stopped altogether one year after the initial diagnosis while she remained clinically and biochemically euthyroid. In July 1997, she developed symptoms and signs of thyrotoxicosis: weight loss, palpitations, and increased sweating. The diagnosis of thyrotoxicosis was confirmed (TSH undetectable, tri-iodothyronine (T3) 2.5 nmol/l (0.7–2.1), and FT4 29 nmol/l). No treatment was given. While on follow-up over the next 2 months her symptoms subsided and she gained weight; thyroid function confirmed hypothyroidism (TSH 84 mU/l, FT4 8.8 nmol/l). In November 1997, although symptomatically she remained well, thyroid function tests showed thyrotoxicosis (TSH undetectable, FT4 30 nmol/l) but she has remained euthyroid on follow-up. Her TMA titre remains the same.

Questions

1. What is the diagnosis?
2. Why is the thyroid function fluctuating?
3. How would you treat this patient?
Answers

QUESTION 1
Autoimmune thyroid disease with fluctuating hypo- and hyperthyroidism.

QUESTION 2
The fluctuations are due to the presence of blocking and stimulating antibodies.

QUESTION 3
There are three possible ways of treating such a patient. The patient must be fully informed about the nature and likelihood outcome of each treatment option:
• following up with serial checks of thyroid function and treatment according to the severity and nature of the thyroid dysfunction
• blocking–replacement therapy with thyroxine and carbimazole or propylthiouracil
• radiiodine treatment with appropriate follow-up.

Discussion
Fluctuating thyroid function can be defined as a spontaneous shift of functional thyroid state from hyperthyroidism to hypothyroidism or vice versa. In autoimmune thyroid disease, thyroid function can fluctuate. Thyroid-stimulating immunoglobulin (measured by the capacity of serum immunoglobulin to stimulate cAMP production in cultured human thyroid cells) stimulates the thyroid gland while blocking antibodies (measured by the degree of inhibition of TSH-stimulated cAMP production of cultured human thyroid cells by serum immunoglobulin) do the opposite. At a particular point, it is the balance between the two antibodies that decides the functional thyroid state. Although not common, similar cases have been reported for hyperthyroidism to hypothyroidism and vice versa. The end point of all reported cases was hypothyroidism, either spontaneously or as a result of treatment, but our patient remained in a euthyroid state without intervention.

Thyrotoxicosis factitia should be considered in the differential diagnosis. Clinically, the presence of goitre, ophthalmopathy or dermopathy is against the diagnosis. In thyrotoxicosis factitia, radioactive iodine uptake of the thyroid gland will be negligible, and serum thyroglobulin and antithyroid antibodies will be undetectable. Also, on biochemical testing, serum T4 is likely to be normal or low with high serum thyroxine and suppressed TSH. The presence of goitre, high serum T4, and high titre of antibodies clearly argue against such a diagnosis in our patient.

The next question is whether or not we can predict such fluctuating behaviour of the thyroid gland. No clear answer is available. Progressive destruction of the thyroid gland or production of TSH receptor blocking antibodies may be responsible for the development of a hypothyroid state in patients with Graves' hyperthyroidism. One can assume that blocking antibody plays a greater role than structural damage of the gland in such cases, otherwise the chance of development of a hyperthyroid phase would be very low. On the other hand, hypothyroid patients with radioiodine uptake are likely to remit, in contrast to those with normal or low uptake. Finally, there may be some yet unidentified factors other than stimulating and blocking antibodies, which are responsible for such fluctuations. It is interesting to note that the very high level of serum TSH at diagnosis and follow-up did not predict the outcome in our patient. Thus, a very high TSH or a very low FT4, does not necessarily mean the patient will have permanent hypothyroidism.

We believe that radioactive iodine is the best way to treat the hyperthyroid phase, with subsequent observation. Our patient's hyperthyroid phase was short lasting and of less magnitude but such a treatment option will be considered in future, if necessary. In the hypothyroid stage, the only option remains replacement with thyroxine to keep the patient euthyroid. Surgery is an alternative option in the hyperthyroid patient after stabilisation with a blocking–replacement regimen.

Final diagnosis
Autoimmune thyroid disease with fluctuating thyroid function as a result of stimulating and blocking antibodies.

Keywords: hyperthyroidism; hypothyroidism; autoimmune thyroid disorder

A newborn with watery diarrhoea

Mohamed Zaki, Khalil B Gallad, Dina G Ramadan, Sameer Ogila

A 35-year-old woman was referred to hospital at 32 weeks gestation because her uterus was large for date. Ultrasound examination done at that time is shown in the figure. At 34 weeks gestation, she gave birth to a baby boy weighing 2.2 kg, who had significant abdominal distension at birth. There was no vomiting. He did not pass meconium but after per rectum examination a large amount of light yellow watery stool was passed, followed by some relief of his abdominal distension. He continued to pass this type of stool. Blood laboratory tests at the age of 2 weeks showed a serum sodium of 131 mmol/l, potassium 3.1 mmol/l, chloride 91 mmol/l and bicarbonate 31 mmol/l. The family had an elder son who had had chronic diarrhoea since birth.

Questions

1. What does the sonogram show?
2. What is the most likely diagnosis?
3. How can the diagnosis be confirmed?
Answers

QUESTION 1
Antenatal ultrasound at 32 weeks gestation showing marked dilatation of foetal intestinal loops and polyhydramnios.

QUESTION 2
The most likely diagnosis is congenital chloride diarrhoea (CCD). The diagnosis was suspected on the basis of maternal polyhydramnios, dilated foetal intestinal loops, premature delivery, absence of meconium, passage of large amount of watery meconium stool since birth, blood tests showing hypochloraemic alkalosis, and the presence of a sibling with chronic diarrhoea since birth. The diagnosis was confirmed in this sibling to be CCD.

QUESTION 3
Confirmation of the diagnosis requires the measurement of both stool and urine electrolytes. In CCD there is a significant increased chloride concentration in stool (exceeding the sum of sodium and potassium) with no chloride in the urine.

Discussion
CCD is a rare autosomal recessive disorder with a worldwide occurrence, although most cases have been reported from Finland and the Middle East. Recently, the CCD gene has been accurately located on chromosome 7. In CCD, there is absence or impairment of active chloride/bicarbonate exchange in both the ileum and colon. The defective chloride absorption leads to osmotic diarrhoea. This malabsorption also explains the metabolic abnormalities seen in these patients.

The clinical presentation varies with the age of the child. During foetal life, significant maternal polyhydramnios occurs as a result of the intrauterine foetal diarrhoea. Antenatal ultrasound demonstrates significant dilatation of the foetal intestinal loops (figure). Almost all patients with CCD are born prematurely, possibly as a result of the intrauterine diarrhoea. Postnatally, these children exhibit significant abdominal distension due to fluid accumulating in their intestine. There is no passage of meconium at birth and stools are profuse and watery. The diarrhoea may passed unnoticed because the fluid is thought to be urine and this can cause delay in diagnosis. Some infants survive for several months without diagnosis. These children fail to grow and their developmental milestones are delayed. Any intercurrent infection, particularly gastroenteritis, can disturb further the delicate water and electrolyte balance and can lead to their demise. In the early neonatal period, the blood biochemistry is within normal limits with occasional acidosis, but after a few weeks, they show the characteristic laboratory finding of hypochloraemic hypokalaemic metabolic alkalosis. Other medical conditions can show similar metabolic abnormalities; especially important are cystic fibrosis and Bartter syndrome. The high faecal chloride (>100 mmol/l), exceeding the sum of faecal sodium and potassium and a chloride-free urine will confirm the diagnosis. The presence of other siblings with CCD, as in the case presented, will allow early identification of similar cases in the family.

Because of the antenatal ultrasonographic findings, the postnatal abdominal distension and the absence of passage of meconium, other surgical conditions may be considered before the correct diagnosis is made. These conditions include intestinal atresia, meconium ileus and aganglionic. Some newborn infants with CCD are subjected to unnecessary laparotomies because of misdiagnosis as one of the above acute surgical conditions. The diagnosis of CCD cannot be verified by amniocentesis since the electrolyte concentration in amniotic fluid is normal. Since the intestinal defect cannot be corrected, life-long treatment with both sodium and potassium chloride solutions is required. The rationale behind this therapy is the normal jejunal absorption of these electrolytes. Such treatment will not correct the diarrhoea but will prevent its secondary effects. Chronic hypovolaemia and hypokalaemia will result in renal tubular dysfunction in some of these children. Children with CCD are at increased risk of developing volvulus postnatally, a complication that may occur at any age from 2 days to 15 years. If the diagnosis is made early and treatment is given adequately, children with CCD can achieve normal physical growth and mental development.

Final diagnosis
Congenital chloride diarrhoea.

Keywords: chloride diarrhoea; newborn; diarrhoea; intestinal atresia
An unusual cause of leg ulceration

D Banerjee, J Grey, K G Harding

A 46-year-old man was referred with a 2-year history of non-healing ulcers on both lower limbs. He had suffered two episodes of deep vein thrombosis, at the ages of 7 and 28 years. He was subsequently admitted to hospital for treatment of pulmonary embolism at the age of 30. A year earlier, he had suffered an uncomplicated inferior wall myocardial infarction. On examination, he had multiple superficial ulcers on both his legs in the gaiter areas (figure). The surrounding skin showed signs of advanced venous insufficiency in the form of venous eczema, lipodermatosclerosis and pigmentation. Duplex imaging of his venous system revealed extensive bilateral post-phlebitic changes. His only medication was warfarin, which he had been advised to take lifelong. His 18-year-old son was also diagnosed to have a deep vein thrombosis and subsequent investigations revealed two of his three children to be suffering from the same condition.

Questions

1 What is the underlying condition?
2 How is this condition managed?
3 How should the ulcers be treated?
Answers

QUESTION 1
This patient was found to have hereditary protein S deficiency (PSD). It is an autosomal dominant disorder, associated with an increased risk for developing thrombosis in heterozygotes; hence the higher prevalence among ethnic groups practising consanguinity. The thrombotic episodes are rare before the age of 15 but it has been reported in a 10-year-old boy. The acquired form of PSD can be due to various disorders including advanced malignancy, chicken pox and other viral infections (eg, HTLV-I). 1

Among the known plasma protein deficiencies associated with venous thrombosis, protein S and protein C deficiencies are the commonest. 1 Protein S is the vitamin K-dependent cofactor of activated protein C (APC) which functions as a potent anticoagulant by degrading activated factors V and VIII in a Ca2+ and phospholipid-dependent reaction. 1 Protein S exists as two forms in plasma, either free and functionally active or complexed with C4b-binding protein and inactive. Inherited resistance to APC was recently discovered as a cause of familial thrombophilia and is now known to be the most common genetic risk factor for venous thrombosis. APC resistance is usually associated with a single point mutation in the factor V gene, which results in substitution of arginine at position 506 by glutamine. The mutation renders factor Va partially resistant to degradation by APC, which leads to a hypercoagulable state and increased risk of venous thrombosis. The previously known inherited deficiencies of antithrombin, protein S, or protein C, are, in western societies, together found in less than 10–15% of thrombosis patients, whereas APC resistance is present in 20–60% of the patients. 4

QUESTION 2
In young patients with recurrent venous thromboembolism in the absence of obvious predisposing factors, it is important to exclude inherited plasma protein deficiencies of protein S, protein C, antithrombin III, plasminogen and fibrinogen.

Learning points
- among the known plasma protein deficiencies associated with venous thrombosis, protein S and protein C deficiencies are the commonest
- protein S deficiency is an autosomal dominant disorder of the clotting system resulting in a hypercoagulable state; an acquired form of the condition can result from various systemic disorders
- protein S deficiency should be suspected in any young patient suffering from deep vein thrombosis or other thrombotic episode and a thrombophilia screen should be performed.
- a thorough family history should be obtained and close family members screened
- recurrent venous thromboses are common in such patients, starting at a very young age, and current practice advocates life-long anticoagulant prophylaxis
- in patients who develop post-phlebitic changes in their limbs, including ulceration, treatment comprises compression and topical wound care

Treatment is predominantly prophylactic, in the form of long-term oral anticoagulation with warfarin. Where its use is contraindicated, for example, in pregnancy, or in the event of warfarin-induced skin reactions, heparin is a suitable alternative. At present, there is lack of consensus regarding the duration of treatment. Current practice seems to favour life-long warfarin therapy.

QUESTION 3
The ulcers are initially treated with topical iodine-impregnated dressing and graduated compression therapy. Venous eczema is treated effectively with topical steroid preparations, usually over 10–12 weeks. After the first few weeks of healing, the compression therapy should be changed to a four-layer bandage system. 2 The ulcers in this patient had healed satisfactorily by the end of 12 weeks of treatment.

Final diagnosis
Protein S deficiency.

Keywords: protein S deficiency; venous thrombosis

A new diabetic patient with an abdominal mass

Boji Varghese, W P Stephens

A 47-year-old woman was referred to the new patient diabetic clinic with typical symptoms of hyperglycaemia. On routine abdominal examination, a mass was found on the left side of the abdomen which was ballottable and bimanually palpable. There was a history of ‘benign retinal tumour’ several years ago which did not need active treatment. Further enquiry revealed this to have been a retinal angioma. Routine laboratory tests on blood and urine were unremarkable except for findings of diabetes mellitus. She went on to have ultrasound scan followed by computed tomography (CT) of the abdomen (figure).

Questions

1. What is the main abnormality seen on the CT scan and what is the radiological diagnosis?
2. What other abnormalities are present on the CT scan?
3. What condition does the patient have?
4. What other abnormalities may occur in this condition?

Figure

CT scan of the abdomen
Answers

QUESTION 1
There is a large solid tumour arising anteriorly from the lower half of the left kidney, with a necrotic centre. There are two solid tumours of the right kidney, with the anterior tumour predominantly necrotic. These appearances are consistent with bilateral hypernephromas.

QUESTION 2
There are multiple bilateral simple renal cysts, multiple pancreatic cysts and a small left adrenal mass.

QUESTION 3
The combination of retinal angioma and bilateral hypernephromas indicates the diagnosis of von Hippel-Lindau syndrome.

QUESTION 4
von Hippel-Lindau syndrome is a rare genetic disorder with multi-organ involvement. The most common features are retinal angiomatosis (51%), haemangioblastoma of the central nervous system (46%), and renal lesions (33%). The pancreatic features of the condition include pancreatic cysts, endocrine deficiency, metastatic islet cell tumour, and acute pancreatitis. The other features are phaeochromocytomas (24%), epididymal cystadenomas and, rarely, carcinoid tumour of the bile duct and deafness due to bilateral endolymphatic sac tumours.

Discussion
von Hippel-Lindau syndrome is an autosomal dominant inherited disease with a prevalence of 1:40 000. The von Hippel-Lindau (VHL) gene has been localised and cloned at human chromosome 3p25-p26.8. The VHL gene product has been found to suppress growth of renal cell carcinoma lines in vitro. The association of von Hippel-Lindau disease with renal cell carcinoma may be explained either by mutation of or loss of both alleles of the VHL gene or by disturbance in the function of the VHL gene product.

Although commonly referred to as cerebello-retinal haemangioblastomatosis, there are other significant clinical associations like renal cell carcinoma and phaeochromocytoma. Our patient was known to have retinal angiomas. Subsequent CT scan of the brain did not show evidence of intracranial haemangioblastoma. Both of the renal tumours were biopsied under CT guidance and histological examination showed adenocarcinoma. Urinary normet-adrenaline screening for phaeochromocytoma was negative.

Although pancreatic cysts are common, pancreatic endocrine or exocrine deficiency is uncommon. Our patient presented with symptoms of diabetes mellitus which was treated by dietary means. There was no clinical suggestion of steatorrhoea. Central nervous system lesions in von Hippel-Lindau disease present as haemangioblastomas and metastatic renal carcinomas. The haemangioblastomas are mainly intracranial (74%), the rest being located in the spinal cord. Retinal angiomatoses present as both capillary and cavernous haemangiomas. The renal lesions include renal angiomas, renal cysts and renal carcinomas. Renal carcinomas are frequently bilateral and, if not diagnosed early, tend to metastasize. Our patient went on to have bilateral nephrectomy and renal replacement therapy with chronic ambulatory peritoneal dialysis. Parenchymal sparing surgery is sometimes used in selected patients with renal carcinoma.

The initial presentation of von Hippel-Lindau syndrome could be to a medical or surgical specialty but more awareness of the syndrome and its associations will lead to early diagnosis. The finding of retinal angiomas or CNS haemangioblastomas should lead to radiological assessment of the kidneys. Screening of first degree relatives will help in early identification of affected individuals.

Formal referral to a medical genetics service will help detailed screening of the patients and their relatives. Medical genetics clinics normally maintain computer registers of such families and are best placed to ensure their adequate prolonged follow-up.

Final diagnosis
von Hippel-Lindau syndrome.

Keywords: von Hippel-Lindau syndrome; renal cell carcinoma; diabetes mellitus

We are grateful to Dr P Norburn for providing CT films.

Fever and dyspnoea in a young man with a rash

Michelle N Dizon, Glenn Matfin

A 36-year-old male smoker presented with a 7-day history of fever, chills and malaise. He admitted to increasing dyspnoea over the past 2 days. There was no history of cough, nausea or vomiting. The patient had developed crops of erythematous pruritic vesicles on his face, trunk, and extremities 5 days prior to admission. He admitted to being exposed to a child with a similar rash, and his own three sons had developed a similar rash.

On examination he appeared to be severely ill. Skin examination revealed multiple vesicular lesions with crusting, mostly on his chest, back, and extremities. An arterial blood gas revealed pH 7.42, pO$_2$ 6.63 kPa, pCO$_2$ 4.03 kPa, and O$_2$ saturation of 87% on room air. He was febrile with a temperature of 39°C. His lungs were clear to auscultation bilaterally. Routine blood tests were normal except for neutrophil leucocytosis (white blood cells of $10^9/l$ with 89% neutrophils, 3.3% lymphocytes, 6.4% monocytes, 0.1% eosinophil, and 0.8% basophil). His chest X-ray is shown in the figure.

Questions

1. What is the differential diagnosis?
2. What treatment would you advise?
3. What are the risk factors and other complications associated with this condition?
Antiviral treatment for varicella infections

**Varicella pneumonia**
- acyclovir, iv 30 mg/kg/day every 8 h or
- vidarabine, iv 10 mg/kg/day every 12 h or
- foscarnet, iv 40 mg/kg/day every 12 h (duration depends on clinical course)

**Varicella in the immunocompromised host**
- acyclovir, iv 30 mg/kg/day every 8 h for 5–7 days or
- vidarabine, iv 10 mg/kg/day every 12 h for 5–7 days or
- foscarnet, iv 40 mg/kg/day every 12 h for 5–7 days

**Varicella in the immunocompetent host**
- acyclovir, po 800 mg five times a day for 5 days

**Box 2**

**Risk factors for adult varicella pneumonia**
- pregnancy
- smokers
- immunosuppressed individuals
- cancer
- older individuals
- severe cutaneous/haemorrhagic rash
- chronic obstructive pulmonary disease

**Box 3**

The identification of several risk factors for adult varicella pneumonia is of special interest for possible chemoprophylaxis (box 3). Reports have show an increased risk for varicella pneumonia in patients after prolonged treatment with corticosteroids, cytotoxic or radiation therapy. In addition, it has been reported that conventional 'low-dose' corticosteroid therapy (<2 mg/kg or 5–20 mg daily), and short-term steroid therapy for acute asthma attacks may predispose patients to disseminated varicella. The US Food and Drug Administration have warned that patients on immunosuppressant doses of corticosteroids should be warned to avoid exposure to chicken pox and, if exposed, obtain medical advice. The UK Committee on Safety of Medicines has recently recommended that all patients taking systemic corticosteroids for purposes other than replacement should be regarded as at risk of severe varicella zoster unless there is a history of previous chicken pox. Even then, a clinical history of chicken pox is not necessarily reliable, and testing of all such patient to identify the seronegative cases at risk might be wise, albeit expensive. The Joint Committee on Vaccination and Immunization has recommended that immunosuppressed patients who have been receiving steroids at a daily dose of 2 mg/kg for more than a week within 3 months of direct contact with chicken pox should be passively immunized with varicella zoster immunoglobins if they do not already have antibodies to varicella zoster. Similar recommendations seem appropriate with other immunosuppressive agents, especially when several agents are combined.

The only identifiable risk factors for this patient was that he had smoked 50 cigarettes/day for the past 10 years and he had a severe cutaneous disease. Further investigation revealed him to be HIV positive with a CD4 count of 200 and his treatment was changed to antiretroviral therapy.

**Principle causes of diffuse nodular shadowing**

- metastatic carcinoma to lungs
- lymphoma
- alveolar cell carcinoma
- sarcoïdosis
- tuberculosis
- fungal diseases (histoplasmosis; cryptococcosis; coccidioidomyicosis; blastomycosis)
- pneumocociosis
- varicella pneumonia
- systemic vasculitis (Wegener’s granulomatosis and peri-arteritis nodosa)
- collagen vascular disease (including rheumatoid nodules and systemic lupus erythematosus)
- septic emboli
- arteriovenous malformations
- haemosiderosis (including Goodpastures’s disease)
- amyloidosis
- cryptogenic organising pneumonia/bronchiolitis obliterans organising pneumonia
- alveolar proteinosis
- pneumocystis carinii pneumonia
- Kaposi’s sarcoma

**Box 1**

**Answers**

**QUESTION 1**

There are many causes of diffuse nodular shadowing on chest X-ray (box 1). The patient's rash was suggestive of chicken-pox. His three sons also had this diagnosis. A diagnosis of presumptive varicella pneumonia was based on the patient's response to intravenous acyclovir and laboratory findings which included negative findings for tuberculosis, legionella, cryptococcosis, and pneumocystis carinii pneumonia. Blood and sputum cultures and sputum cytology were also negative. The patient refused fiberoptic bronchoscopy. After 7 days of treatment with acyclovir, his condition greatly improved and he was discharged.

**QUESTION 2**

Acyclovir is preferred over vidarabine for treatment. It has been more effective in shortening the cutaneous course of varicella infection in the immunocompromised patient. Other advantages of acyclovir are reduced haematopoietic and neurological toxic reactions, shorter infusion time, and increased solubility. Vidarabine and foscarnet have also been used to treat varicella infection, but with much less success. The recommended doses of these drugs are listed in box 2.

**QUESTION 3**

The only identifiable risk factors for this patient was that he had smoked 50 cigarettes/day for the past 10 years and he had a severe cutaneous disease. Further investigation revealed him to be HIV positive with a CD4
count of 0. He denied any history of intravenous drug use or high-risk sexual behaviour. Eight months later, this patient developed varicella retinopathy and progressive outer retinal necrosis (PORN syndrome), which resulted in permanent visual loss. PORN is a distinct form of necrotizing herpetic retinopathy that has been reported with increasing frequency in AIDS patients. Varicella zoster virus is currently the only agent that has been associated with the disease.

Various complications of varicella infection may occur (box 4). The most common and serious complication is varicella pneumonia.

Discussion

Varicella is usually a benign childhood disease, while in the adult it may be complicated by pneumonia with high morbidity and mortality rates. Varicella is one of the most common transmittable diseases. However less than 2% of 3–4 million annual cases in the US occur in adults. The most common complications of adult varicella are pulmonary manifestations, especially pneumonia (incidence rate 10–50%). Ninety per cent of pulmonary manifestations of varicella occur after the age of 19 years, mainly in the third decade. Untreated adult varicella pneumonia is fatal in approximately 10% of cases.

Pneumonia occurs early in the course of varicella, within 1–6 days after the onset of the rash. Varicella pneumonia should be considered in any adult with chicken pox who complains of dyspnoea, cough and fever. Physical findings usually correlate poorly with the degree of pneumonia.

Chest X-rays of varicella pneumonia can vary; abnormal findings are seen in about 16% of cases with primary varicella. Findings may include a patchy, diffuse air-space consolidation or diffuse interstitial infiltrates that may be nodular, with the severity correlating with the diffuseness of the rash. The infiltrate can be associated with a proteinaceous exudate, oedema and hyaline membrane formation which can progress to respiratory distress syndrome. In the later stages, diffuse pulmonary microcalcifications of 2–3 mm in diameter have been described.

Aggressive and early treatment with acyclovir seems to prevent the potentially catastrophic consequences of varicella pneumonia. Oral acyclovir chemoprophylaxis may have some benefit in high-risk populations with chicken pox.

Final diagnosis

Varicella pneumonia.

Keywords: chicken pox; varicella pneumonia; acyclovir

Box 4

Other complications of varicella infection
- encephalitis
- Guillain-Barre syndrome
- glomerulonephritis
- arthritis
- hepatitis
- pancreatitis
- myocarditis
- venous thrombosis
- thrombocytopenia
- orchitis
- conjunctivitis, iritis, uveitis, keratitis
- Henoch-Schonlein purpura
An unusual rash
