Classic diseases revisited

Lambert-Eaton myasthenic syndrome

Udaya Seneviratne, Rajith de Silva

The Lambert-Eaton myasthenic syndrome (LEMS) is an antibody-mediated autoimmune disorder of neuromuscular transmission characterised by muscle weakness, hyporeflexia or areflexia and autonomic dysfunction.

History

In 1953 Anderson and colleagues reported the case of a 47-year-old man with a bronchial neoplasm, progressive proximal muscle weakness and hyporeflexia who developed prolonged apnoea following administration of succinylcholine. They concluded that there was "strong clinical evidence for believing that the severe muscle weakness was of the myasthenic type". The patient showed the features of what we know today as LEMS.

At a meeting of the American Physiological Society in 1956, Lambert, Eaton and Rooke presented a report on six patients with defective neuromuscular transmission associated with malignant neoplasms. They identified that some of the clinical and electrophysiological features were different from what was expected in myasthenia gravis. Subsequently in 1957, Eaton and Lambert summarised the clinical and electrophysiological characteristics of the myasthenic syndrome.

Aetiology and epidemiology

LEMS can be broadly divided into two groups depending on whether it is associated with carcinoma or not. However, the electrodiagnostic and clinical characteristics do not differ in those two groups.

Approximately 60% of LEMS patients have associated small cell carcinoma of the lung (SCLC). The incidence of LEMS in patients with SCLC is 3%. Its association with other malignancies has been reported less commonly (box 1).

O'Neill and colleagues found that in a patient presenting with LEMS the possibility of having an underlying SCLC falls sharply after two years and becomes negligible after 4 to 5 years. Both groups of LEMS patients have an autoimmune basis suggested by the presence of organ-specific and non-organ-specific antibodies. Various autoimmune diseases and other immunological disorders have been reported in association with LEMS, which provides further evidence for autoimmunity (box 2).

In LEMS, about 25% of patients have autoimmune diseases and 35–45% are positive for organ-specific antibodies. The prevalence of autoantibodies is higher in the group with no underlying carcinoma. When both groups are considered together, more than 80% of patients present over the age of 40. Generally, carcinoma-associated LEMS patients tend to present at an older age than LEMS without carcinoma (mean ages 57.9 and 48 years, respectively). If the diagnosis of LEMS is made before the age of 30 it is unlikely to be associated with an underlying tumour.

The sex differences in the two groups are less clear. O'Neill et al, in their series, found a statistically significant male predominance in the group without associated carcinoma and when both groups were considered together. Male predominance was also seen in the series published by Lennon et al in 1982. However, Gutmann and colleagues in 1992 did not find such a sex difference in their study (table 1). This discrepancy in the carcinoma-associated group could be due to changing patterns in smoking, which is a strong risk factor for the development of SCLC.

Immunogenetics

There is a significant association with HLA-B8 in both groups of LEMS, which appears to be stronger in the group with no associated carcinoma. The frequency
Malignancies other than SCLC known to be associated with LEMS

- lymphoproliferative disorders
- carcinoma of the breast, colon, stomach, gall bladder, kidney, and bladder
- adenocarcinoma of the lung, pancreas, and prostate
- intrathoracic carcinoid

Immunological disorders associated with LEMS

Pathophysiology

The release of neurotransmitters at presynaptic motor nerve terminals of the neuromuscular junction and autonomic neurones depends on the influx of calcium through the voltage-gated calcium channels (VGCC). IgG from patients with LEMS has been shown to block the VGCCs. These antibodies result in symptoms by decreasing the release of neurotransmitters. They occur in both groups of LEMS patients.

The VGCCs are classified as L, N, P/Q, R, and T depending on their electrophysiological and pharmacological properties. They are found in various tissues, including neuronal cells, neuroendocrine cells and the cardiovascular system. In the nervous system they are present at the neuromuscular junction, autonomic neurones, and the central nervous system, particularly the cerebellum. Different types of VGCCs may co-exist at one synapse.

Acetylcholine release from mammalian motor nerve terminals depends on N, P and Q type VGCCs. In LEMS, antibodies directed against these VGCCs decrease the release of acetylcholine, resulting in muscle weakness. N, P and Q type VGCCs play a key role in the neurotransmitter release at autonomic neurones.

Antibodies from patients with LEMS have been shown to block the VGCCs. These antibodies interfere with neurotransmitter release from postganglionic sympathetic and parasympathetic neurones by down-regulating mainly the P/Q type of VGCCs, which probably explains the mechanism of autonomic dysfunction.

The SCLC tumour cells have been shown to express VGCCs of L, N and P/Q sub-types. In SCLC-associated LEMS they appear to provide the antigenic stimulation for antibody production which cross-reacts with the VGCCs in the nervous system. The resulting down-regulation in VGCCs would account for the clinical features.

Clinical features

Lambert and colleagues in their original series gave a classical description of the clinical features, and these were supplemented in subsequent reports (box 3). The cardinal clinical characteristics described by Eaton and Lambert were weakness and fatigability of muscles, temporary increase in strength after voluntary exercise, depressed or absent tendon reflexes, marked sensitivity to curare (as in myasthenia gravis) and relatively poor response to neostigmine. Tendon reflexes show marked potentiation after sustained contraction of the appropriate muscle for 10–15 seconds.

The onset of symptoms is usually gradual and insidious. Occasionally it could be subacute. The commonest presenting symptom is leg weakness. Mild and transient cranial nerve symptoms such as diplopia, drooping of eye lids and dysphagia are reported by around 70% of patients. However, cranial nerve signs are very rare except for ptosis (54%) and weakness of neck flexion (34%). Although patients complain of diplopia, ophthalmoplegia on examination is extremely unusual in LEMS.

Autonomic symptoms are experienced by 80% of patients. Severe autonomic dysfunction may be found on testing even when symptoms are minimal. Both the sympathetic and parasympathetic systems are affected in LEMS.

Investigations

ANTIBODIES TO VGCCs

Over 90% of patients belonging to both groups of LEMS have antibodies against P/Q type VGCCs. This finding appears to be particularly strong in carcinoma-associated LEMS where almost all patients are positive for antibodies against the P/Q type of VGCCs. Antibodies against N type VGCCs are found

517 of the immunoglobulin G (IgG) heavy chain marker G1m(2) is also found to be increased in both groups.

of the immunoglobulin G (IgG) heavy chain marker G1m(2) is also found to be increased in both groups.
in less than 50% of patients when both groups of LEMS are considered together.\textsuperscript{30, 37} However, when considered separately, these antibodies are found more commonly in LEMS associated with primary lung cancer.\textsuperscript{30} Therefore, the detection of N-type antibodies may increase the possibility of finding an underlying primary lung cancer (table 2).\textsuperscript{30}

**ELECTRODIAGNOSIS**

Electrophysiological tests are useful for diagnosis as well as for monitoring the course of the illness. Compound muscle action potential (CMAP) after a supramaximal stimulus, postactivation potentiation (increase in the CMAP amplitude immediately after maximal voluntary contraction), repetitive nerve stimulation, and single fibre electromyography often help to differentiate LEMS from myasthenia gravis (table 3).\textsuperscript{3, 35, 38–42} Postactivation exhaustion (decrease in the CMAP amplitude 2–4 minutes after maximal voluntary muscle contraction) is seen in both the LEMS and myasthenia gravis. The results should be interpreted taking the entire picture, including the clinical presentation, into consideration.

The analysis of end-plate potentials and miniature end-plate potentials obtained from in vitro microelectrode studies can also help to differentiate LEMS from myasthenia gravis.\textsuperscript{38, 43}

**EDROPHONIUM TEST**

The edrophonium test may be positive in LEMS but the response is usually weaker than that in myasthenia gravis.\textsuperscript{4}

**Treatment options**

**3,4-DIAMINOPYRIDINE**

3,4-Diaminopyridine improves muscle strength and autonomic disturbances in LEMS without serious side-effects.\textsuperscript{7, 44} It is used for symptomatic relief and is effective in both groups of LEMS. It blocks voltage-gated potassium channels which leads to prolongation of the action potential at motor nerve terminals and the open time of the VGCCs.\textsuperscript{45} This process results in increased influx of calcium enhancing quantal neurotransmitter release.

The optimal dose of 3,4-diaminopyridine can vary from 5 mg tid to 25 mg qid. Its beneficial effects are felt about 20 minutes after an oral dose and last for about 4 hours. The maximum response occurs in 3 to 4 days due to cumulative effect. The commonest side-effect is peri-oral paraesthesia. Seizures have been reported in overdosage and rarely at therapeutic dosage.\textsuperscript{46}

**GUANIDINE**

Guanidine is an effective drug for symptomatic relief but its use is restricted by serious side-effects, including bone marrow toxicity, nephrotoxicity, hepatotoxicity, dermatitis and atrial fibrillation.\textsuperscript{47, 48}

**ANTICHOLINESTerase DRUGS**

Lambert, in his first report, noted the poor response of his patients to neostigmine.\textsuperscript{7} Anticholinesterases alone produce mild or no improvement in LEMS. However, they seem to potentiate the effects of 3,4-diaminopyridine.\textsuperscript{7} Anticholinesterases can be used in combination with 3,4-diaminopyridine,\textsuperscript{7} or low-dose guanidine,\textsuperscript{49} to produce symptomatic relief.

**STEROIDS AND IMMUNOSUPPRESSIVES**

The beneficial effect of long-term therapy with prednisolone has been shown in individual case reports.\textsuperscript{47, 50} A retrospective study has shown that prednisolone combined with azathioprine is more effective than prednisolone alone in LEMS.
with no associated carcinoma. Although there are no prospective randomised controlled trials, it is reasonable to consider this option for long-term therapy in patients unresponsive to 3,4-diaminopyridine.

**PLASMA EXCHANGE**

Repeated plasma exchanges have been shown to produce significant symptomatic improvement in LEMS patients, reaching a peak at two weeks and subsiding by 6 weeks. It is effective in both groups of LEMS. Plasma exchange is particularly helpful in patients with severe weakness.

One of the disadvantages of plasma exchange is lack of selectivity. Protein A immunoadsorption is a technique used to remove IgG from plasma selectively. The success of this method has been reported in a patient resistant to plasma exchange and intravenous immunoglobulin.

**INTRAVENOUS IMMUNOGLOBULIN**

The benefits of intravenous immunoglobulin (IVIG) were first shown in individual case reports. In a double-blind, placebo-controlled, cross-over trial involving LEMS patients with no carcinoma, IVIG (1 g/kg body weight/day for 2 days) produced a significant increase in muscle strength peaking at 2 to 4 weeks and effects lasting up to 8 weeks. The clinical response was associated with a significant fall in antibodies to VGCCs. IVIG can be used as an alternative to plasma exchange in patients with severe weakness.

There are no data available on IVIG therapy in LEMS associated with carcinoma; it may well also be effective in this group as the underlying disease mechanism is antibody mediated.

The treatment strategy in individual patients mainly depends on the severity of symptoms, the degree of response to symptomatic treatment, and the presence or absence of an associated malignancy (box 4).

**Management of LEMS associated with SCLC**

These patients can be treated with 3,4-diaminopyridine for symptomatic relief. The specific treatment of the underlying tumour usually results in improvement or remission of symptoms. In such patients the only further treatment required may be continuation of 3,4-diaminopyridine. When the specific tumour therapy fails to resolve symptoms, further treatment with prednisolone should be considered. Those who present with severe weakness will benefit from plasma exchange or IVIG.

**Management of LEMS with no associated cancer**

3,4-Diaminopyridine therapy is beneficial in this group and, if successful, no additional treatment is required. Those who have not responded should be treated with prednisolone and/or azathioprine as long-term therapy.
remission is achieved, prednisolone could be tapered to the minimum maintenance dose. If the weakness is severe, plasma exchange or IVIG should be considered.

Investigating for an underlying malignancy is an important step in the management of LEMS. In the majority of patients, symptoms of LEMS precede the diagnosis of underlying malignancy, the risk of which becomes low after 4 to 5 years.1 However, in high-risk patients such as smokers, it is worth undertaking regular screening for SCLC even after this length of time.20
