**CASE REPORTS**

Vacuum assisted closure system in the management of enterocutaneous fistulae

C Cro, K J George, J Donnelly, S T Irwin, K R Gardiner

**Background:** A very important yet often troublesome element in the conservative management of enterocutaneous fistulae is the protection of the surrounding skin from contact with the effluent. This report describes the successful use of a vacuum assisted closure (VAC) system in dealing with this problem.

**Methods:** The results of using the VAC system were studied in three patients with moderate or high volume output enterocutaneous fistulae where conventional treatment had failed to prevent skin excoriation.

**Results:** The VAC system was found to be highly effective in controlling fistula effluent and in promoting healing of excoriated skin in all three patients. Complete healing of the fistula was also achieved in two of the three patients.

**Conclusion:** The VAC system can be an effective and economically viable method of containing fistula effluent and protecting the skin of patients with enterocutaneous fistulae. Contrary to conventional thought, the VAC system may also actually promote healing of the fistula.

Enterocutaneous fistulae are abnormal communications between the gastrointestinal tract and the skin. They can be related to underlying disease such as inflammatory bowel disease, appendicitis, diverticular disease, intestinal ischaemia, perforation of duodenal ulcer, or develop postoperatively due to iatrogenic intestinal injury or anastomotic failure. Enterocutaneous fistulae have a significant mortality and morbidity as a result of associated sepsis, malnutrition, and fluid imbalance.

Management of the skin surrounding enterocutaneous fistulae is a difficult challenge because of the effect of moisture and chemical irritation on the skin. A key element in the conservative management of enterocutaneous fistulae is the protection of the surrounding skin from contact with the effluent.

We describe the use of the Vacuum Assisted Closure (VAC) system (KCI Medical, Witney, Oxfordshire, UK) in three patients who developed postoperative enterocutaneous fistulae (table 1).

**CASE REPORTS**

**Case 1**

A 64 year old man was transferred with enterocutaneous fistula through midline and right iliac fossa abdominal wounds after preoperative radiotherapy, low anterior resection of rectum, and two subsequent laparotomies for suspected anastomotic leakage and intestinal obstruction respectively. The high volume output (more than 1 litre/day) and increasing skin excoriation led to repeated dislodgement of wound drainage bags. A sponge in VAC system was applied to both wounds using a Y connector to control intestinal losses and to protect the skin. After five weeks, drainage and skin condition had improved and the VAC system was replaced with a wound drainage bag. By three months, the fistula output had decreased to less than 200 ml/day and complete wound healing was achieved by five months.

**Case 2**

A 54 year old woman developed a high output (1 litre/day) proximal enterocutaneous fistula through a midline abdominal wound created at the time of laparotomy and small bowel resection for adhesive intestinal obstruction and reopened 18 days later to drain an intra-abdominal abscess and resect an ischaemic segment of small intestine. Abnormal contouring of her abdominal wall from multiple previous operations prevented adherence of a wound management bag. The VAC system used with a Jackson Pratt drain controlled the fistulous output effectively but left her bed bound. After five weeks, the skin condition improved and the fistulous output decreased and the VAC system was replaced by a Foley catheter connected to a drainage bag. After four months, the fistulous output fell to less than 200 ml/day. She has since undergone further laparotomy, resection of the fistula, and intestinal reanastomosis with complete healing of her abdominal wound.

**Table 1** Summary of fistula characteristics and effect of VAC treatment

The foam dressing is connected to an adjustable vacuum source via a canister which collects the exudate. Low level vacuum (about 125 mm Hg) is applied either continuously or cyclically (five minutes on and two minutes off) and has been proved to be more effective than 24 hours of treatment. The VAC system could prove to be an extremely valuable tool to study changes in the wound microcirculation by analysing timed aliquots of the fluid removed. The pump currently costs around £3800 to purchase or £15.00 a day to hire. In addition to this, a pack of 10 dressings will cost between £150 to £235. This has to be balanced against the savings produced by reductions in length of hospital stay, frequency of dressing changes, nursing time, and by accelerated healing. Enterocutaneous fistula is usually considered a contraindication to the use of the VAC system.

In conclusion, it has been considered that the use of sub-atmospheric pressure is contraindicated in the treatment of enterocutaneous fistulas as it has been believed that it may delay closure of the fistula and may cause damage to internal organs. This report describes the successful use of the VAC system in controlling fistula effluent and in promoting healing of excoriated skin (by keeping skin dry and free from exudate) in three patients with enterocutaneous fistulae. The VAC system may also promote healing of the fistula.
