Does patient knowledge affect the colorectal cancer risk in ulcerative colitis?

J A Eaden, K Abrams, J F Mayberry

Objective: Formal efforts to improve patient education are associated with fewer disease complications in a number of conditions. The possible relationship between knowledge about ulcerative colitis and its cancer risk, and the development of colorectal cancer using a previously developed and validated instrument—the Crohn’s and colitis knowledge (CCKNOW) score—were investigated.

Methods: The 24 item CCKNOW questionnaire was mailed to patients known to have developed colorectal cancer as a complication of ulcerative colitis (cases) and to colitics from the Leicestershire inflammatory bowel disease patient database who had not developed cancer (controls).

Results: The mean (SD) CCKNOW scores for cases was 8.21 (3.02) and for controls was 8.27 (4.3). These scores did not differ significantly between cases and controls (difference 0.06, 95% confidence interval (CI) −1.7 to 1.3, p=0.9). There were four times as many members of the National Association of Crohn’s and Colitis (NACC) in the control group compared with the cancer group and patients who are members of NACC achieve statistically significantly higher scores than non-members (11.6 v 7.8, p=0.05, 95% CI −0.1 to 7.6). However, after adjusting for NACC membership, the CCKNOW score did not appear to be associated with having developed cancer (odds ratio 1.04, 95% CI 0.92 to 1.18, p=0.5).

Conclusions: The CCKNOW scores were comparable in cases and controls. Thus, in a retrospective study, no evidence has been demonstrated of an association between patient knowledge and the risk of developing colorectal cancer in patients with ulcerative colitis. However, knowledge may have been increased in cases as a direct result of having had colorectal cancer as a complication of ulcerative colitis.
cases were alive and approval of consultants in charge of patient care was sought before mailing the CCKNOW score to them. Seventy questionnaires were posted to cases. One hundred controls (matched for age and sex) identified from the Leicestershire IBD patient database were also mailed a CCKNOW score. These controls were not the same patients as those used in developing the CCKNOW score described in the previous paper.7

The level of statistical significance between the mean scores of cases and controls was estimated using an independent two sample t test and 95% confidence intervals were calculated.11 Assessment of the statistical significance of an association between being a case and a variety of potentially important characteristics was undertaken using logistic regression in SPSS. The study has a power of 70% to detect an odds ratio of 3.0 at the 5% significance level assuming an average exposure in the control group of 30%.

RESULTS

After one mailing 42 questionnaires were returned by the cases, who had colorectal cancer complicating ulcerative colitis (response rate 60%) and 44 were returned from the controls, who had ulcerative colitis (response rate 44%). The characteristics of cases and controls are shown in table 1. There was no significant difference in the two groups in terms of age, gender, and the length of time spent in full time education. However, there were four times as many members of the National Association of Crohn’s and Colitis (NACC) in the control group compared with the cases.

The mean score of the patients who had developed colorectal cancer complicating ulcerative colitis was 8.21 with a SD in their score of 3.02 (range 0–13). Controls had similar scores with a mean of 8.27 (SD 4.3, range 0–22). An independent two sample t test showed that there was no statistically significant difference between the mean scores of the two groups (difference 0.06, 95% confidence interval (CI) −1.7 to 1.5, p=0.9).

Scores were analysed according to membership of the NACC. The mean (SD) score for patients who were members, irrespective of being a case or a control, was 11.6 (5.3) whereas the mean scores for non-members was 7.8 (3.2). This difference was statistically significant (difference 3.8, 95% CI −0.1 to 7.6, p=0.05). We investigated the possibility of NACC membership having a bias and so the analysis was repeated after excluding the self help groups members. This reduced the mean scores in both groups but to a greater extent in the control group. The new mean scores were 8.13 for cases and 8.34 for controls respectively—that is, patients who had had colorectal cancer now achieved higher knowledge scores than those who had not. However, this difference is still not statistically significant (difference 0.69, 95% CI −0.8 to 2.2, p=0.4). Therefore, NACC members were included in the rest of the analyses.

Logistic regression analysis found no statistically significant associations between scores on the CCKNOW, gender, age, and years spent in full time education. Being a member of NACC was associated with a reduction in the risk of developing colorectal cancer by 78% and scoring more than 11 on the CCKNOW reduced risk by 39% but these findings did not reach statistical significance (p=0.07 and p=0.42 respectively) possibly due to the relatively small numbers. After adjusting for NACC membership, the CCKNOW score did not appear to be associated with having developed cancer (odds ratio 1.04, 95% CI 0.92 to 1.18, p=0.5).

To determine whether those cases who were diagnosed at a later Dukes’s stage of colon cancer were those who had poorer knowledge levels, the CCKNOW scores were stratified according to the Dukes’s stage of cancer at diagnosis among the cases who responded to the questionnaire (table 2). The data shows no correlation between the CCKNOW score and cancer stage at diagnosis.

The response rate among cases and controls was 60% and 44% respectively. The CCKNOW questionnaire was mailed only once. Hospital records were used to identify whether cases were deceased. These were not as accurate as was hoped and in two instances the questionnaire was returned by a relative stating that the patient had died. Concern was raised that this may have been the reason why other questionnaires among cases had not been returned. In order to avoid any possible anxiety to relatives the non-responders were not sent any further questionnaires. Consequently, so that both groups were treated uniformly, the CCKNOW questionnaire was not posted to non-responding controls.

The medical records of the cases had already been reviewed in a previous study.10 These data was reviewed to investigate whether there were any differences in the responding and non-responding cases. There were no statistically significant differences between responders and non-responders in terms of gender, extent of disease, and stage of cancer when diagnosed.

Considering questions from the general knowledge section of the questionnaire individually, both cases and controls (74% and 68% respectively) knew that just because they may have been symptom-free for three years they were not cured of their condition but only a fifth (21% and 23%) knew that IBD runs in families. A similar number in each group (only 14% and 16%) realised that a child with IBD may not grow to be as tall as his or her friends, with the remaining responders actually believing that they may be either less intelligent or may not live beyond

the age of 45. A difference between the two groups was noted in the question concerning whether IBD can affect parts of the body other than the bowel. Only 26% of cases answered this correctly compared with 46% of the controls.

Regarding medication there was some confusion between the types of drug used to treat IBD. A similar number (57% and 55%) understood the role of immunosuppressive drugs but more controls knew that azathioprine was an example of such a drug (18% vs 5%). Many more controls (73% vs 55%) knew that sulphasalazine was used to reduce the frequency of relapse and were aware that it can reversibly reduce male fertility (27% vs 5%). Concerning steroids an equivalent number (50% of cases and 55% of controls) knew that they can be administered rectally and intravenously as well as orally.

As far as complications of IBD are concerned, perhaps not surprisingly more cases (29% vs 18%) were aware which patients were at increased risk of bowel cancer and therefore who should be under surveillance. However, even with a personal history of cancer complicating colitis this is still a surprisingly small number. Fourteen per cent of cases thought that if they passed blood in their stool it meant that they definitely had bowel cancer compared with 9% of controls. Again more cases understood what a fistula was (43% vs 25%) and had a better knowledge of bowel anatomy with 41% knowing the location of the terminal ileum compared to 30% of controls.

**DISCUSSION**

The level of knowledge in patients with ulcerative colitis is the same irrespective of whether they had developed colorectal cancer or not. Thus patient knowledge does not appear to affect the risk in patients with ulcerative colitis. We expected that cases would have significantly lower knowledge levels than controls as we anticipated that poor knowledge could be a risk factor. We based this on the assumption that patients with poor knowledge would be less likely to attend surveillance colonoscopies and comply with medication. Both of these factors have been shown to have a protective effect against cancer in colitis.6 10 11

However, we feel that our study could be biased. There is a strong possibility that the knowledge level of cases has been significantly modified by the process of having colorectal cancer. It is likely that cases would have learnt more about their condition as a direct result of having cancer and the need to undergo surgery. Our data would support this view in that cases had notably better scores on anatomy questions and more knew who was at risk of bowel cancer compared with the control group. Controls achieved the same or better scores in other sections, knowing more about 5-aminosalicylic acid medications and IBD affecting other parts of the body. It may be of significance that controls were more knowledgeable about sulphasalazine and mesalazine as these medications may be protective against colorectal cancer in ulcerative colitis.6 12 13

It was not possible to investigate differences between the cancer survivors who responded to the study and patients who had died from cancer complicating colitis. However, it is worth considering the possibility that patients who died may be those who were diagnosed at a later stage and these may also be the cases who were less knowledgeable. The study could be improved by obtaining further data from the medical records of the cases and controls such as disease duration and severity of disease as this could ostensibly affect the level of knowledge. Data such as missed colonoscopy and outpatient clinic appointments could be extracted and a comparison made between responding and non-responding cases. This would investigate the hypothesis that non-responders were those who were less compliant. However, obviously no data could be obtained concerning non-responding patients’ knowledge levels.

Our findings are based on a small sample size and this limits any interpretation of the results. However, it is interesting to note that there were more members of the NACC in the control group. NACC members achieved significantly higher scores on the questionnaire which agrees with the findings in our previous study. We have shown a positive but non-significant association between membership of NACC and a reduction in the risk of developing colonic cancer. If this hypothesis is correct, that protection be mediated through better knowledge or is it simply because they are a highly motivated group who attend surveillance and comply with medication? This is an interesting concept that merits further investigation through the continued use of the CCKNOW score in clinical practice.

The data showed no correlation between the CCKNOW score and the stage of colon cancer at diagnosis. However, this study was conducted retrospectively. Thus the current level of knowledge does not necessarily reflect the level of knowledge when the cancer was diagnosed. Ideally this study should be conducted prospectively with all patients completing the CCKNOW score at regular intervals, such as outpatient consultations. The CCKNOW could be used in its 12 item form (giving patients the two different versions alternately and periodically adding new questions) to prevent patients from learning answers. In this way we could obtain a true indication of the knowledge level of cases before developing cancer and be able to assess whether poor knowledge is a significant risk factor. However, such an approach would take at least 10 years and possibly longer as 30 to complete as the vast majority of colorectal cancers in ulcerative colitis occur after the first decade of disease.4 10 14 Easier outcomes to assess would be frequency of flare ups or the number of missed outpatient and colonoscopy appointments. These measures of compliance could be surrogate markers for the likelihood of developing cancer but this has not yet been assessed. This concept could easily be investigated in the future to determine whether knowledge can be used as a measure of such behaviours as adherence to therapeutic regimens or medical outcomes including reduced frequency of complications.

Wallenberg’s lateral medullary syndrome

A previously healthy 55 year old man presented with acute onset of nausea, vomiting, diplopia, and vertigo. He had hoarseness of voice, difficulty in swallowing, and nasal regurgitation of food and water. He had a tendency to fall to the right side. On neurological evaluation he had cerebellar type of dysarthria, right sided gaze evoked nystagmus, paralysis of palatal and pharyngeal movement, and absent gag reflex on the right side. He also had Horner’s syndrome on the right side. There was no motor weakness, deep tendon reflexes were normal, and both plantars were flexor. There was loss of pain and temperature sensations over left half of face, arm, and leg and presence of cerebellar signs on the right side. The rest of the examination including fundus was unremarkable. A provisional diagnosis of right sided lateral medullary syndrome was made. Unusually in this case, the contralateral half of face was involved. This may be due to involvement of the contralateral trigeminothalamic tract that crosses the side of the lesion within the dorsal medulla. Alternatively medullary neurons may receive input from the contralateral face. Investigations revealed high fasting (9.1 mmol/l) and postprandial (11.3 mmol/l) plasma glucose concentrations, a glycated haemoglobin of 10.5%, total cholesterol of 7.0 mmol/l, low density lipoprotein of 4.9 mmol/l, and high density lipoprotein of 0.9 mmol/l. Magnetic resonance imaging revealed a small infarct in right lateral medullary region (fig 1). The patient was managed with insulin, aspirin, and atorvastatin. His condition steadily improved over the next two weeks and he was nearly asymptomatic six months after discharge.
