**CASE REPORT**

Infected endocarditis from *Enterococcus faecalis* complicating colonoscopy in Hayde’s syndrome

M Giusti de Marle, A Sgreccia, E Carmenini, S Morelli

A case of infective endocarditis from *Enterococcus faecalis* after colonoscopy in a patient with aortic stenoinufficiency and bleeding intestinal angiodysplasia (Heyde’s syndrome) is reported.

A 77 year old man with aortic stenoinufficiency presented with enterorrhagia and underwent a colonoscopy, which showed normal findings. Fifteen days later he developed a moderate degree of fever. Blood cultures were positive for *E faecalis*. An echocardiogram showed aortic valve vegetations, and infective endocarditis was diagnosed and successfully treated by antibiotics. Some months later, intestinal bleeding recurred and intestinal resection was performed. Histopathology showed angiodysplasia.

In patients with Heyde’s syndrome antibiotic prophylaxis should be considered before colonoscopy.

Current international guidelines consider colonoscopy to be a low risk procedure for infectious complications. In fact, published cases of infective endocarditis after proctosigmoidoscopy or colonoscopy are quite uncommon (table 1). *Enterococcus* is the most frequent causative agent of infective endocarditis complicating proctosigmoidoscopy, particularly in patients with underlying valvular heart lesions (table 1).

We report a case of infective endocarditis from *Enterococcus faecalis* after colonoscopy in a patient with aortic stenoinufficiency and bleeding intestinal angiodysplasia (Heyde’s syndrome).

**CASE REPORT**

A 77 year old man was admitted to our department because of enterorrhagia and progressive anaemia. On physical examination he was pale, dyspnoic, and an aortic systo-diastic murmur (Levine grade 3) was heard. Laboratory examination showed microcytic hypochromic anaemia (haemoglobin 62 g/l). An echocardiogram showed severe left ventricular hypertrophy and a calcific aortic valve with moderate-severe stenoinsufficiency. Upper gastrointestinal endoscopy, colonoscopy, computed tomography of the abdomen and pelvis, and arteriography of gastrointestinal vessels did not disclose the origin of the bleeding. No antibiotic prophylaxis was performed before procedures. Fifteen days after colonoscopy, the patient became febrile (body temperature up to 40.1°C). A repeat echocardiogram showed two small and mobile vegetations on the right and non-coronary aortic cusps, and transoesophageal echocardiogram confirmed this finding. Three blood specimens for culture were drawn and within seven days all cultures were positive for *Gram positive cocci*, identified as ampicillin and high level gentamicin susceptible *E faecalis*. A diagnosis of infective endocarditis was made and a four week therapeutic trial with ampicillin 24 g/day and gentamycin 1 mg/kg three times a day was performed. The patient’s condition progressively improved and laboratory findings normalised (haemoglobin 124 g/l). The patient was scheduled for elective heart valve surgery and was discharged. A few weeks later, he was hospitalised again because of a new episode of enterorrhagia. Angiography was performed and the site of the bleeding was shown at the level of the ascending colon. Segmental resection of the ascending colon was performed and histological examination of the intestine showed mucosal vascular ectasias (angiodysplasia). The postoperative course was uneventful and the patient was discharged. Three months later he died from hypovolaemic shock because of a new episode of enterorrhagia.

**DISCUSSION**

*E faecalis* makes up a significant portion of the normal gut flora of almost all humans, and enterococci account for approximately 5% to 18% of all cases in most series of infective endocarditis. The probability of enterococcal endocarditis increases in the presence of valvular heart abnormalities, gastrointestinal neoplasia, and surgery, including dental manipulation. The most common portals of entry for enterococcal bacteria include the urinary tract, abdominal sepsis, decubitus ulcers, burns, infection of diabetic foot, and

Summary points

- Heyde’s syndrome is characterised by aortic stenosis and bleeding gastrointestinal angiodysplasia.
- Bleeding gastrointestinal angiodysplasia is caused by deficiency of the largest plasma multimers of von Willebrand factor.
- Aortic valve replacement cures gastrointestinal bleeding and normalises plasma levels of the largest plasma multimers of von Willebrand factor.
- Diagnosis of vangiodysplasia is made by colonoscopy and biopsy with corroborating histological documentation.
- Bleeding gastrointestinal angiodysplasia could be regarded as risk factor for enterococcal bacteraemia during colonoscopy.
- Antibiotic prophylaxis should be considered in patients with suspected Heyde’s syndrome undergoing colonoscopy.

vascular catheters. The gastrointestinal tract has also been reported as portal of entry for enterococci.

In our patient, the probable source for enterococcal bacteraemia was the colonoscopic procedure, whereas both arteriography and upper gastrointestinal endoscopy were very unlikely with regard to this. Indeed, the only endoscopic procedure reported in causal association with enterococcal infective endocarditis is sigmoidoscopy. No cases of enterococcal infective endocarditis after colonoscopy have been described in the literature, as far as we know. On the other hand, three cases of non-enterococcal infective endocarditis have been reported, and only two of them were attributable to colonoscopy. After colonoscopy, the bacteraemia rate is low, up to 4%. Thus, antibiotic prophylaxis is not recommended even in patients with an increased risk of endocarditis, as our patient may be considered as being affected by severe valvular heart disease. Bleeding intestinal angiodysplasia could be regarded as an additional risk factor, since bleeding from mucosal damage during endoscopy may increase because of acquired platelet dysfunction in patients with Heyde’s syndrome. Stenotic aortic valve would accelerate the clearance of the largest plasma multimers of von Willebrand’s factor, which mediates the adhesion of platelets to the subendothelium of damaged blood vessels. The reversibility of platelet dysfunction as well as the disappearance of recurrent bleedings after aortic valve replacement strongly suggests a causal link between valvular stenosis and intestinal haemorrhages.

Conclusions

Enterococcus faecalis endocarditis may occur on native aortic valve after colonoscopy in patients with Heyde’s syndrome. Thus, appropriate antibiotic prophylaxis should be considered in patients with suspected Heyde’s syndrome undergoing colonoscopy.
