The renin-angiotensin-aldosterone system in heart failure for the non-specialist: the past, the present and the future

Christopher Orsborne,1 Parminder S Chaggar,1,2 Steven M Shaw,1,2 Simon G Williams1,2

ABSTRACT
Heart failure is one of the major public health challenges facing the Western world. Its prevalence is increasing as the population ages and modern techniques are implemented to manage cardiac disease. In response, there has been a sustained effort to develop novel strategies to address the high levels of associated morbidity and mortality. Indeed, agents that target the renin-angiotensin-aldosterone system (RAAS) have transformed the way in which we manage heart failure. Despite this, mortality in heart failure is poorer than in many malignancies and a large burden of morbidity and recurrent hospitalisation remains. Here, we review the role of RAAS modulation within the field of systolic heart failure. In particular, we provide practical guidance on using current RAAS blockade agents and focus on the recent emergence of new agents that promise additional substantial benefit to those living with left ventricular systolic dysfunction.

INTRODUCTION
Heart failure is increasingly prevalent in the Western world, affecting 1%–2% of the total population. It is more common in the elderly, where prevalence is as high as 10% in those aged over 70 years.1 Despite advances in treatment, heart failure is associated with a poor prognosis, which is worse than many common malignancies, high rates of acute hospital admissions and severely impaired quality of life.2,3 However, epidemiological studies suggest that mortality and hospitalisation rates in heart failure are slowly improving because of modern medical and device therapies.4–5 In particular, the impact of treatments that target the renin-angiotensin-aldosterone system (RAAS), which underpins the neurohormonal pathogenesis of heart failure, has been significant. ß-Blockers (BBs), angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs) and mineralocorticoid receptor antagonists (MRA) have quickly been adopted into international guidelines because of substantial evidence of morbidity and mortality benefit provided by large, multicentre randomised controlled trials (RCTs).6 A new class of drug to treat heart failure has been awaited for over 15 years during which progress has largely been made through refining existing treatment strategies and the advent of device therapies. However, the recent PARADIGM-HF trial offers a promising novel treatment in the form of an angiotensin receptor and neprilysin inhibitor (ARNI), sacubitril-valsartan, a new class of RAAS blockade.7 In order to appreciate the position of this novel agent it is necessary to understand the impact that RAAS modulation has already had in the field of systolic heart failure and the challenges that remains. Here, we discuss the historical and contemporary role of RAAS modulation in order to contextualise the significance of new agents.

THE NEUROHORMONAL BASIS OF HEART FAILURE
The RAAS is a central feature in the pathophysiology of heart failure. Adaptations in this system occur in response to an inability to meet the demands of vital organ systems. The RAAS is activated by renal hypoperfusion and sympathetic activation. The key product of this cascade is angiotensin II (ATII), which has multiple systemic-wide effects that are initially compensatory but subsequently exacerbate the heart failure syndrome. An overview of the role of the RAAS in heart failure is outlined in figure 1. The sympathetic nervous system (SNS) is also intrinsic to the neuroendocrine pathophysiology of heart failure and is closely interlinked with the RAAS. Initially, catecholamine excess temporarily increases cardiac output via inotropic and chronotropic effects but subsequently exacerbate myocardial ischaemia, hypertrophy and arrhythmia.8 Counterregulatory mediators, the best understood of which are the natriuretic peptides (NPs), oppose the RAAS and SNS. A-type natriuretic peptide and B-type natriuretic peptide (BNP) are secreted in response to myocardial wall stretch, promoting vasodilatation and natriuresis and inhibit the SNS and RAAS. These peptides are partly degraded by neprilysin, the enzyme that is central to a new class of pharmacologically significant therapy for heart failure.1 In summary, although RAAS and SNS adaptations initially improve cardiac output, they progressively overwhelm the opposing vasodilator and natriuretic mediators and propagate the heart failure syndrome (figure 2). This review discusses the foundations of modern aoeart failure treatment, more recent developments and the future of RAAS modulation in heart failure. The key studies are summarised in table 1.

THE PAST
Angiotensin-converting enzyme inhibitors
ACE inhibitors are notable as the first class of drug to demonstrate significant mortality benefit in the landmark trials, CONSENSUS and SOLVD. CONSENSUS, a double-blind RCT, compares
enalapril with placebo in patients with New York Heart Association (NYHA) class IV heart failure symptoms and an ejection fraction (EF) <35%. At randomisation, patients were established on diuretics and digoxin, in addition to spironolactone in 52.5%. In an incredibly sick study population with 1-year mortality of 52% in the placebo arm, enalapril reduced all-cause mortality by 31% (relative risk = 0.69, p = 0.001). CONSENSUS was the first to demonstrate a significant all-cause mortality benefit in heart failure and following this success, SOLVD treatment goes on to examine the role of enalapril in a much larger and critically, less symptomatic cohort. Here, >85% of those included were in NYHA class II or III and active treatment was associated with a significant risk reduction in all-cause mortality of 16% (risk reduction 16% 0.84, 95% CI 3% to 26%, p < 0.0036) and a 26% lower risk of heart failure-related hospital admissions or death (relative risk 0.74 95% CI 34% to 18%, p < 0.0001). These studies demonstrate similar overall withdrawal rates in the active treatment and placebo groups, although hypotension, dizziness and cough are identified as side effects of ACE inhibitor therapy.9-10

ACE inhibitors were clearly beneficial in moderate-to-severe symptomatic heart failure but the SOLVD investigators go on to assess ACE inhibitor efficacy in patients with minimal symptoms despite EF <35%. The SOLVD-Prevention study recruited patients with minimally symptomatic heart failure (NYHA class I–II), and not based on any antiheart failure medications. Even in the absence of significant symptoms, enalapril demonstrates a 20% reduction in the combined outcome of heart failure mortality or heart failure hospitalisation (95% CI 9% to 30%, p <0.001).11

The early ACE inhibitors studies mostly include patients with a background of ischaemic heart disease and several studies have examined the role of ACE inhibitors specifically in the postmyocardial infarction (MI) heart failure population. Three large well-designed RCTs, Survival and Ventricular Enlargement (SAVE), Trandolapril Cardiac Evaluation (TRACE) and Acute Infarction Ramipril Efficacy examine the role of ACE inhibitors post-MI (AIRE); each using a different ACE inhibitor (captopril, trandolopril and ramipril, respectively).12-14 A methodically sound systematic review of the three trials demonstrated that in the 5966 study patients, all-cause mortality decreased from

Figure 1  Schematic overview of the renin-angiotensin-aldosterone system and its manifestations in heart failure as well as the mechanism of action of currently recommended pharmacological agents. ADH, antidiuretic hormone; ACE-i, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; MRA, mineralocorticoid receptor antagonists; BB, β-blocker.

Figure 2  Schematic of the interaction between the renin-angiotensin-aldosterone system (RAAS) system and the natriuretic peptides and how the RAAS modulators and angiotensin receptor nephrilysin inhibitors (ARNIs) influence the balance. ACE-i, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; MRA, mineralocorticoid receptor antagonists; BB, β-blocker.

A significant reduction in all-cause mortality and cardiac mortality, significant decrease in NYHA class

29.1% to 23.4% (OR 0.74, 95% CI 66 to 83, p < 0.0001), hospitalisation from 15.5% to 11.9% (OR 0.73, 95% CI 0.63 to 0.85, p < 0.0001) and re-infarction from 13.2% to 10.8% (OR 0.8, 95% CI 0.69 to 0.94, p = 0.0057) over a 31-month follow-up period.

Maximal dose titration is a key feature of all of the RCTs of heart failure therapies and is recommended in all international guidelines for clinical practice. ATLAS, an RCT examining the effects of ACE inhibitor dosage, demonstrates significant benefits from high-dose as opposed to low-dose lisinopril. Compared with low-dose therapy, high-dose treatment (mean doses 4.5 mg ± 1.1 mg vs 33.2 mg ± 5.4 mg) demonstrates an 8% reduction in all-cause mortality (HR 0.92, 95% CI 0.82 to 1.03, p = 0.128) and a significant 12% reduction in the combined outcome of death and hospitalisation (HR 0.88, 95% CI 0.82 to 0.96, p = 0.002). Crucially, there is no significant increase in withdrawals from study with high-dose treatment indicating an acceptable side-effect profile at fully optimised doses.

In summary, ACE inhibition is associated with significant reductions in mortality, morbidity and hospitalisation for heart failure with an acceptable side-effect profile. This effect is applicable to those with, and without, symptoms and crucially, is most pronounced at the highest tolerated dose. ACE inhibition therefore carries a class I, level A recommendation, in international guidelines as first-line treatment in patients with EF < 40% (figure 3). Table 2 provides practical guidance for clinicians using ACE inhibitors in heart failure.

### Spironolactone

With the role of ACE inhibitors established, there was an initial assumption among clinicians that the use of MRAs in addition to ACE inhibitors would be likely to precipitate renal complications. However, the role of spironolactone as an ‘add-on’ treatment to ACE inhibitors in heart failure was established in the RALES trial; a double-blind RCT including patients with NYHA class III or IV heart failure, already treated with ACE inhibitors and with EF < 35%. Spironolactone reduced the risk of death from any cause by 30% (relative risk 0.7, 95% CI 0.6 to 0.82, p < 0.001) and hospitalisation due to worsening heart failure by 35% (relative risk 0.65, 95% CI 0.54 to 0.77, p < 0.001), while NYHA symptom class also improved. Only 14/822 patients (2%) in the spironolactone arm compared with 10/841 (1%) in the placebo arm had serious adverse events involving hyperkalaemia (p = 0.42). As anticipated there was a significant increase in the number of men complaining of breast symptoms with spironolactone (1% vs 10%, p < 0.001), but overall, adverse event rate was equivalent to placebo (p = 0.17). The trial

of treatment and in all studies BBs are well tolerated. Practical guidance on the use of BB in heart failure is available in table 3.

### Angiotensin receptor blockers

Although the concept of ACE inhibition was proven in heart failure failure, basic science studies demonstrated that ATII could be produced independently of ACE. It was therefore logical to pursue more selective receptor blockade using ARBs.23 24 The key questions for clinicians are first, whether an ACE and ARB in combination is more effective and as safe as ACE inhibition alone and second whether ARBs could be used instead of ACE inhibitors in those who encounter intolerable side effects.

ARB and ACE (added)

VALHEFT and CHARM-added are the two most influential studies that examine the ACE inhibitor and ARB combination. Both are randomised, double-blind RCTs that compare the combination of an ACE inhibitor and an ARB versus the combination of an ACE inhibitor and placebo.

VALHEFT randomised 5010 patients with NYHA class II–IV heart failure and an EF<40%. After 23 months follow-up, there was no significant decrease in all-cause mortality, cardiovascular mortality or hospitalisation rates. Similarly, in CHARM-added which also included NYHA class II–IV patients with an EF<40%, there was no significant all-cause mortality benefit (HR 0.89, 95% CI 0.77 to 1.02, p=0.086) despite a significant reduction in the combined end point of heart failure admissions and cardiovascular death (HR 0.85, 95% CI 0.75 to 0.96, p=0.01). The safety profile of combination therapy is also concerning with excess adverse events leading to discontinuation of the study drug in the ARB-arm of both trials, mainly due to dizziness, hypotension, hyperkalaemia and renal impairment. Of particular concern, severe hyperkalaemia defined as serum potassium of >6 mmol/L occurred in 3% of patients in comparison to 1% in the placebo arm (p<0.0001).23 26

ARB instead of ACE

CHARM-alternative examines the role of ARBs in patients with NYHA class II–IV heart failure and EF<40% by selectively recruiting those who could not tolerate an ACE inhibitor, mainly due to cough, hypotension or renal dysfunction. A total of 2028 patients were recruited for 33 months and were treated with either ARB or placebo in a double-blind fashion. The combined outcome of heart failure hospitalisation or cardiovascular death significantly reduced with an adjusted HR of 0.70 (95% CI 0.60 to 0.81, p<0.0001). However, there was no significant decrease in all-cause mortality and the incidence of ARB discontinuation was significantly higher than the placebo group (3.7% ARB vs 0.9% placebo, p<0.0001) due to hypotension, renal dysfunction and hyperkalaemia.27 Therefore, ACE inhibitors retain their position as the first-line RAAS blockade agent of choice in heart failure and ARBs should only be prescribed if there are definitive side effects directly attributable to ACE inhibitors. In the case of ACE inhibitor cough, since cough is a common and non-specific symptom, it is recommended a direct causal link with the ACE inhibitor be established with a re-challenge before changing to an ARB.

If ARBs are used in clinical practice dose up-titration is essential. The HEAAL study compares high-dose and low-dose losartan (50 vs 150 mg) in a randomised fashion and demonstrated a reduction in all-cause mortality of 6% (HR 0.94, 95% CI 0.84 to 1.04, p=0.24) and a reduction in heart failure-related hospital admissions of 13% (HR 0.87, 0.76–0.98, p=0.025) with high-dose therapy. Withdrawal from the study in both treatment arms was comparable despite the higher dose.28 Overall, the combination of an ACE inhibitor and ARB reduces the risk of hospitalisation, but is not associated with all-cause mortality benefit and confers a significant side-effect profile in comparison to ACE inhibition alone. ARB treatment in those that are truly intolerant of ACE inhibitors is an acceptable strategy, on the basis that ARBs reduce heart failure hospitalisation compared with placebo in this select population. Clearly, ACE inhibitors and ARBs are not interchangeable in this context and have distinct roles in clinical practice. ARBs are strictly reserved for patients with definite ACE inhibitor side effects. Indeed, if a patient develops heart failure while established on an ARB for another indication, switching to an ACE inhibitor should be considered if it has not been tried previously. Practical guidance on the use of ARBs is summarised in table 2.

### THE PRESENT

Recent advances in RAAS blockade in heart failure have focused on the role of eplerenone. The RALES trial demonstrated the efficacy of MRAs in severely symptomatic heart failure and the EMPHASIS-HF trial goes on to examine the role of eplerenone.
in patients with heart failure and mild symptoms. Patients with NYHA class II symptoms, an EF<35% and a recent heart failure-related hospitalisation or elevated BNP were randomised to eplerenone or placebo. The trial was stopped early after 21 months as it demonstrated significant benefit on the combined end point of cardiovascular death or first heart failure hospitalisation (HR 0.63, 95% CI 0.54 to 0.74, p<0.001). Significant reductions were also demonstrated in secondary end points of all-cause mortality (HR 0.76, 95% CI 0.62 to 0.93, p=0.008) and cardiovascular mortality (HR 0.76, 95% CI 0.62 to 0.93, p=0.01). Furthermore, the role of eplerenone post-MI has been established in the EPHESUS study, a large multicentre RCT. Patients with an EF<40% and clinical features of heart failure or diabetes were randomised 3–14 days post-MI to eplerenone or placebo. Both all-cause mortality (relative risk=0.85, 95% CI 0.75 to 0.96, p=0.008) and the combined end point of death from any cause or cardiac hospitalisation were significantly reduced (relative risk=0.87, 95% CI 0.79 to 0.95, p=0.002). Eplerenone increases serum creatinine and potassium levels in both trials; however, there are no serious adverse events secondary to hyperkalaemia in either trial and the rate of serious hypokalaemia was significantly reduced. Unlike spirono-
lactone, there is no increase in severe symptoms compared with placebo. Interestingly in EPHESUS, the adverse event rate was higher in the placebo arm including one death attributed to hyperkalaemia. Patients in both trials were already benefitting from maximally tolerated doses of BBs and ACE inhibitors or ARBs so the positive effects of eplerenone are seen in addition to optimised baseline therapy. Guidance on the use of MRAs in clinical practice is available in table 4.

THE FUTURE
Angiotensin receptor and neprilysin inhibitors
Thus far, there has been an emphasis on inhibition of the RAAS. However, the pathology of heart failure is an imbalance between regulatory and counterregulatory mechanisms (figure 2). The best-characterised mediators opposing the deleterious effects of RAAS activation in heart failure are the NPs. Therefore, inhibitors of neprilysin, an enzyme that degrades NPs have been used in novel treatments for heart failure.

Initial trials of an ACE inhibitor and a neprilysin inhibitor combination, omapatrilat, in heart failure and hypertension cohorts were unsuccessful due to an unacceptably high incidence of angiooedema. This relates to excess bradykinin accumulation since both ACE and neprilysin inhibition block the bradykinin degradation pathway. However, since ARBs do not increase bradykinins, combination with an ARB has recently been studied in the PARDIGM-HF trial. PARDIGM-HF recruited patients with an EF<40% and NYHA class II–IV heart failure and elevated BNP despite optimal anti-heart failure therapy and randomised them to enalapril or the ARNI, sacubitril-valsartan. The study featured a novel ‘run-in’ period where patients received both treatments in turn for a short period to ensure that patients could tolerate both drugs at the required doses prior to randomisation. Ninety-three per cent of patients were established on BB therapy, 55.6% on MRAs and 7% had received cardiac resynchronisation therapy.

The primary outcomes of the study were all significantly reduced in the ARNI arm with reduction in death from cardiovascular causes or first heart failure hospitalisation from 26.5% to 21.8% (HR 0.8, 95% CI 0.73 to 0.87, p<0.001), death from cardiovascular causes 16.5% to 13.3% (HR 0.8, 95% CI 0.71 to 0.89, p=0.001) and crucially, all-cause mortality from 19.8% to 17% (HR 0.84, 95% CI 0.76 to 0.93, p<0.001). Importantly, adverse effects were also closely examined. Of note, during the ‘run-in’ period, 12% of the ARNI arm withdrew due to adverse events particularly cough, hyperkalaemia, renal dysfunction or symptomatic hypotension although, overall more ‘run-in’ withdrawals were seen in the enalapril arm. In the main study, sacubitril-valsartan caused significantly more symptomatic hypotension but significantly less hyperkalaemia, cough and renal impairment than enalapril. Although, a non-significant increase in the incidence of angiooedema was seen in the ARNI arm (19 events vs 10 events, p=0.13), there were no reports of airway compromise in the study as a whole.

In summary, the emergence of ARNIs is a pivotal development in the management of systolic heart failure. In direct comparison to ACE inhibitors, ARNIs demonstrate a significant benefit in mortality, morbidity and hospitalisation rates. This is impressive in the context of patients already optimised with BB, MRAs and device therapy that confer significant benefits of their own. The undeniable fact is that switching patients from the established gold standard of ACE inhibitors to ARNIs will significantly improve morbidity and mortality in patients with systolic heart failure; this is the first new class of agent in anti-heart failure therapy since the emergence of BBs 15 years ago. Consequently, ARNIs are likely to precipitate a paradigm shift in the management of heart failure.

ARNI have recently been incorporated into guidance documents. In the UK, the National Institute for Health and Care Excellence recommend sacubitril-valsartan in patients with symptomatic chronic heart failure with EF<33% and who are already taking stable doses of ACE inhibitors or ARBs. It is recommended that the novel therapy should only be initiated by heart failure specialists with access to a multidisciplinary heart failure team. Meanwhile, in the recently updated European Society of

Adapted from McMurray et al and the British National Formulary. MRA, mineralocorticoid receptor antagonists; NSAIDs, non-steroidal anti-inflammatory drugs; NYHA, New York Heart Association.

Cardiology guidelines for the management of heart failure, sacubitril-valsartan receives a class IB recommendation in patients with an EF<35% and elevated NPs (BNP ≥150 pg/mL or plasma N-terminal pro B-type natriuretic peptide (NT-proBNP) ≥600 pg/mL, unless there has been a heart failure-related admission in the previous 12 months, when the cut-offs are BNP ≥100 pg/mL or NT-proBNP ≥400 pg/mL), which remain symptomatic despite an ACE inhibitor, BB and MRA at the highest tolerated dose.35 36

Sacubitril-valsartan is available in three doses 26/24 mg, 51/49 mg or 103/97 mg twice daily. A starting dose of 26/24 mg twice daily is appropriate when the ARNI is replacing a low-dose ACE inhibitor or ARB or when initial systolic blood pressure is <110 mm Hg, this should be increased every 3–4 weeks as tolerated; 51/49 mg twice daily is recommended in those who are already stabilised on an ACE inhibitor or ARB, and this should be increased after 2–4 weeks as tolerated. A lower starting dose of 26/24 mg is necessary in moderate hepatic impairment (Child-Pugh B classification) or severe renal impairment (estimated glomerular filtration rate<30 mL/min/1.73 m²). In all patients the dose should be increased, as tolerated, at the intervals stated above to a maximum dose of 103/97 mg twice daily. Sacubitril-valsartan is contraindicated in severe hepatic impairment, previous angiooedema with an ACE inhibitor/ARB, pregnancy, breastfeeding, a systolic blood pressure of <100 mm Hg and concomitant use of aliskiren in patients with diabetes.

Critically, sacubitril-valsartan should not be administered together with an ACE inhibitor or an ARB. To minimise the risk of angioedema inferred by simultaneous ACE and neprilysin inhibition, sacubitril-valsartan should only be commenced after a 36-hour period free from administration of ACE inhibitors. Patients should be warned of commonly occurring side effects that include nausea, diarhoea, gastritis, anaemia, hypoglycaemia, hypokalaemia and vertigo.18 35

ARE WE MAKING THE MOST OF THE EVIDENCE BASE?
A central tenet of all the above trials is that the active agent is up-titrated to the maximum tolerated dose. Several studies discussed above highlight the importance of maximal dose titration of ACE inhibitors and ARBs, particularly with regard to effects on mortality and hospitalisation. Despite the overwhelming evidence base, there is a substantial body of evidence indicating that in current clinical practice prognostic antihcet failure therapies are underutilised and suboptimally titrated.16 17 28 Therefore, it is as important to ensure that patients with heart failure receive the available evidence-based treatments at optimal doses, as it is to adopt new advances in disease management, which are also likely to require careful optimisation.

CONCLUSION
Since the 1980s, heart failure management has changed dramatically. There has been a stepwise progression in evidence-based agents, many of which act via the RAAS, which have transformed the prognosis and morbidity in patients with heart failure. ARNs are the latest development in this chain and represent the first new pharmacological strategy in heart failure since the emergence of BBs. It is poignant therefore, at this pivotal moment in time, to reflect on the progress made thus far before looking forwards to the next step. In particular, it is of concern that there is a substantial body of evidence arguing that as clinicians we are not currently making the most of the treatments already available in the antihcet failure armament. Even in the presence of such a robust evidence base, it is clear that many patients are either, not on the recommended agents, or more commonly, not on the maximal tolerated dose. Therefore, it is our responsibility as clinicians to critically evaluate new evidence and adopt appropriate new therapies, and also to ensure...
5. Which of the following statements is true regarding the use of BBs in heart failure?

A. BB should be stopped if the resting heart rate falls below 60 bpm.
B. When commencing BB for heart failure, a temporary increase in diuretics may be required.
C. BBs are contraindicated in all patients with chronic obstructive pulmonary disease.
D. In BB-naïve patients, BB should be commenced immediately during an acute heart failure decompensation.
E. In patients established on BB, the BB should always be discontinued during an acute heart failure decompensation.

that we do not forget the foundations on which novel treatments are developed and continue to maximise the benefits of established therapies.

Contributors CO wrote the manuscript and designed the figures. PSC designed the structure of the manuscript wrote sections of the manuscript and critically reviewed the manuscript. SMS and SGW provided senior critical review of the manuscript.

Competing interests SGW has received honorarium from Novartis for advisory work.

Provenance and peer review Not commissioned; externally peer reviewed.
