Summary

A case of persistent tricuspid incompetence due to acute myocardial infarction is described. Review of the literature has revealed no similar case.

THE appearance of a systolic murmur for the first time during the course of acute myocardial infarction is common, often transient, and generally due to mitral incompetence (Heikkila, 1967). Less frequently, rupture of the interventricular septum is responsible (Holloway, Whalen and McIntosh, 1965).

A patient has recently been observed who developed a systolic murmur due to tricuspid incompetence on the eighth day following acute inferior myocardial infarction. The patient recovered and was in good health 1 year later, but with persistent signs of tricuspid incompetence. Review of the literature has revealed no similar case.

Case report

A 75-year-old woman was admitted with a 3-day history of central chest pain. Before this she had been treated for hypertension with methyl dopa. No heart murmur was noted on previous medical examinations and there was no history of acute rheumatism. Examination revealed a regular heart rate of 50/min and a blood pressure of 85/50 mmHg. The apex beat was palpable in the fifth intercostal space in the anterior axillary line. There was no murmur on auscultation of the heart. The jugular venous pressure was elevated and crepitations were heard at the lung bases but there was no peripheral oedema. The ECG revealed junctional rhythm and acute, transmural, inferior myocardial infarction. The heart appeared enlarged on chest X-ray. Atrial fibrillation developed on the fourth day but there was no cardiac murmur. Digitalization was instituted with improvement. A pansystolic murmur, accentuated by inspiration, appeared on the eighth day together with prominent 'V' waves in the jugular venous pulse.

A chest X-ray at this time revealed pulmonary venous congestion without change in heart size or configuration from the initial X-ray. However, a third X-ray taken three days later revealed marked increase

FIG. 1. Chest X-ray on admission.

in the size of the right atrium. There was no clinical radiologic evidence to suggest pulmonary embolism. The heart reverted spontaneously to sinus rhythm on the nineteenth day and she was discharged on the twenty-first day with persistent signs of tricuspid incompetence. When last seen, 1 year following the acute infarct, she was active and symptom free but the signs of tricuspid incompetence were present and screening of the heart revealed persistent but less prominent enlargement of the right atrium.

Comment

Review of the literature has revealed one previous case of tricuspid incompetence as a result of myocardial infarction due to a ruptured tricuspid papillary muscle (Eisenberg and Suyemoto, 1964). The patient did not survive. Heikkila (1967) mentioned the appearance of this complication in one of his patients, but no details were given. The extreme rarity of this complication is related to the infrequency of infarction of the right ventricle and to

FIG. 2. Chest X-ray on the eleventh day, showing the development of right atrial enlargement.

the fact that the three tricuspid valve leaflets generally receive chordal insertions from more than one group of papillary muscles (Eisenberg and Suyemoto, 1964). The course and clinical findings in the present patient point to papillary muscle dysfunction or rupture as the cause of tricuspid incompetence which developed in the course of acute myocardial infarction. This patient is unique in that she survived this rare complication of myocardial infarction but with persistent tricuspid incompetence.

Summary

The simultaneous presentation of Hodgkin's disease and multiple myeloma is described. This is rare as only one previous case appears to have been documented.

Speculations as to the aetiology are discussed as well as the significance of the presentation.

Introduction

Second malignancies develop in 1.6-2.2% (Cannellos *et al.*, 1975) of patients with Hodgkin's disease following therapy. Multiple myeloma complicating

treated Hodgkin's disease has been described (Rosner and Grunwald, 1974). A case is now reported in which these two neoplasms occurred simultaneously.

Case report

A 60-year-old male was admitted to a hospital with night sweats and weight-loss of 6 months' duration. An axillary lymph node biopsy revealed nodular sclerosing Hodgkin's disease. He was referred to The London Hospital and was staged
