Summary: An unusual presentation of disseminated mucormycosis as acute renal failure in a patient without any predisposing condition, is reported. The diagnosis was established at autopsy.

Introduction

Mucormycosis is an invasive fungal infection caused by members of the family Mucoraceae (genera Mucor, Rhizopus and Absidia). It was first elaborated as a clinical entity by Gregory *et al.*¹ in 1943, in association with diabetes mellitus. Subsequently its occurrence in patients with diabetic ketoacidosis, leukaemia, lymphomas, multiple myeloma, uraemia, burns, renal transplant recipients and those on corticosteroid and immunosuppressive therapy has been described.^{2–4} We report the clinicopathological features of a case of disseminated mucormycosis which presented with acute renal failure.

Case report

A 53 year old man presented with hiccoughs and vomiting for 15 days, 10–15 tarry stools with fresh blood for 3 days, oliguria followed by anuria for 3 days and altered sensorium for 2 days. He was a chronic smoker with a long history of cough with mucoid expectoration.

Physical examination revealed marked pallor and digital clubbing. Pulse was 120/min, blood pressure 90/50 mm Hg and temperature 37°C.

Investigations showed haemoglobin of 3.41 mmol/l, total leucocyte count $57.6 \times 10^9/l$ with 74% neutrophils and 26% lymphocytes. Blood biochemistry showed sodium 110 mmol/l, potassium 5.0 mmol/l, calcium 1.88 mmol/l, inorganic phosphorus 1.45 mmol/l, urea 57.2 mmol/l, creatinine 353.6 $\mu\text{mol/l}$. Blood culture was sterile. Chest X-ray showed emphysematous lung fields with a patchy consolidation in the right upper zone. Ultrasonographic examination of the abdomen revealed bilaterally

enlarged kidneys with normal echo pattern and regular outlines. Upper gastrointestinal endoscopy revealed oesophagitis and 2 ulcers in the stomach besides several healed erosions.

Peritoneal dialysis was instituted twice to combat the uraemia. On the 10th day in hospital the patient developed fever and abdominal tenderness which progressed to peritonitis, septicaemia, shock and death.

At autopsy the lungs showed changes of anthracosis and emphysema with an abscess, 1.5 cm in diameter, in the right upper lobe. Microscopic examination of the abscess revealed a necrotic centre containing septate hyphae of Mucor with right angled branching pattern and invading the blood vessels in the adjoining lung tissue (Figure 1). Both kidneys had a variegated appearance showing large infarcts, ischaemic cortical necrosis, haemorrhages and exudates on the surface.

The artery and vein at the hilum, on both sides, showed approximately 90% occlusion of their lumina by thrombi. Microscopic examination of the kidney tissue revealed infarction and granulomatous inflammation with central necrosis, vasculitis and thrombosis of large and medium sized arteries and veins (Figure 2). Mucor hyphae were present in the interstitium, blood vessels, glomeruli and tubules. The hyphae were not seen in the giant cells, but were seen in the necrotic areas in the centre of the granulomas. The urinary bladder showed petechial haemorrhages over the mucosa, but no fungal hyphae. The pancreas was enlarged and adherent to the surrounding structures with areas of necrosis, and microscopic examination revealed Mucor hyphae. There were features of peritonitis with exudates over the kidneys, adrenals and mesentery containing the fungus. The intestines revealed ischaemic changes in the ileum and colon with vascular occlusion by thrombi containing fungal hyphae.

Figure 1 Photomicrographs from the lung showing: (A) mass of tangled fungal hyphae in the abscess cavity. A long hypha showing right angled branching is indicated (arrow); (B) vascular invasion by the fungi (Grocott stain $\times 600$).

Thus this patient had disseminated mucormycosis with the primary focus most probably in the lung and secondary involvement of the kidneys, pancreas, intestines, mesentery and peritoneum.

Discussion

Fungi of the family Mucoraceae exist ubiquitously in the soil and are not usually pathogenic to human beings unless the host defences are compromised. Though diabetes mellitus, lymphomas, leukaemias and other immuno-suppressed states are the usual predisposing conditions, the disease is known to occur in apparently normal individuals.⁵ Our patient also did not have an obvious illness which could have facilitated the disseminated *Mucor* invasion.

The spectrum of mucormycosis includes its presentation as rhinocerebral, rhinoorbital, paranasal, cerebral, pulmonary, cutaneous, gastrointestinal, aural and disseminated disease.² Disseminated mucormycosis as was present in our patient is invariably fatal and the diagnosis is seldom made during life due to the non-specificity of symptoms and signs. Parfrey, in a

recent series, reported widely disseminated disease in 3 out of the 33 cases of mucormycosis reviewed by him,² whereas Meyer *et al.* had earlier found it in 10 out of the 26 cases with underlying leukaemia of lymphoma.³

Pulmonary mucormycosis may present as an isolated involvement or as part of the disseminated disease, wherein the lung is often the primary site of infection. Pulmonary vascular thrombosis and infarction have been present almost uniformly and it has been suggested that the cavities as seen in our patient represent liquefaction of pulmonary infarcts.⁵

Renal failure which was the predominant presenting feature in this patient is not common in mucormycosis, although renal involvement in the disseminated disease³ and isolated renal mucormycosis have both been reported.^{7,8} The characteristic lesions of *Mucor* invasion involving the hilar as well as smaller vessels in both the kidneys with associated thrombosis, infarction, ischaemic cortical necrosis and granulomatous inflammation seen in this case were responsible for acute renal failure. The inappropriately low haemoglobin level was secondary to the complicating gastrointestinal haemorrhage, which by itself was not the primary cause of renal failure. Gastrointestinal

Figure 2 Photomicrographs of the kidney showing: (A) thrombotic occlusion and vasculitis of the hilar vessel (H & E $\times$ 60); (B) granulomatous inflammation consisting of epithelioid cells, giant cells and a few lymphocytes with *Mucor* hyphae in an extracellular location (H & E $\times$ 150).

mucormycosis is rare and usually involves the stomach, with the colon next in frequency.^{9,10} Involvement of the ileum, colon, pancreas and peritoneum as seen in this patient are also unusual features.

The diagnosis of mucormycosis should be made on histological grounds, as positive cultures may merely

indicate the presence of this ubiquitous saprophyte, and not necessarily tissue invasion. Culture is required, however, to identify the fungal species.² Recognition of the disease in life requires a high index of suspicion, and timely therapy with amphotericin B may aid in the survival of these patients with otherwise fatal disease.³
