Summary: Gastrointestinal involvement in neurofibromatosis is well recognised. We present an unusual manifestation of gastro-intestinal neurofibromatosis – chronic gastrointestinal bleeding from extensive smooth muscle tumours.

Introduction

Although gastrointestinal involvement in neurofibromatosis is common, it is not often symptomatic. One of the least frequent gastrointestinal associations of neurofibromatosis is multiple smooth muscle tumours. We report such a case which also illustrates the need to search for cutaneous manifestations of neurofibromatosis in patients with chronic unexplained gastrointestinal blood loss.

Case report

A 20 year old labourer presented in 1974 with abdominal discomfort and symptoms of anaemia. He had been taking aspirin for headaches for two weeks but had not noticed any change in bowel habit. His haemoglobin was 5.5 g/dl with an MCV of 70 fl. He was a life-long non-smoker and non-drinker and there was no relevant past or family history. Examination revealed that he had melaena and he required blood transfusion. A barium meal, sigmoidoscopy and barium enema were all normal. Over the next 12 months his haemoglobin remained stable and a provisional diagnosis of bleeding secondary to aspirin ingestion was made.

In 1980 he had a further melaena, again having taken aspirin for several days previously. His haemoglobin was 6.4 g/dl and he was transfused and given a total dose iron infusion. A barium meal was normal. A year later his iron deficiency anaemia recurred this time without aspirin ingestion or melaena.

Gastroscopy, duodenal biopsies and flexible sigmoidoscopy were normal. A small bowel enema was reported as showing very extensive Crohn's disease with mucosal irregularity and stricturing involving the distal jejunum and most of the ileum. He remained remarkably well apart from mild abdominal discomfort for the next four years when he again presented with a melaena. His haemoglobin was 5.5 g/dl and he required transfusion. Gastroscopy and serum orosomucoids were normal. A double contrast barium enema was normal and a repeat small bowel enema showed further extensive changes of Crohn's disease especially of the jejunum. Soft nodules were noted on his trunk and biopsy of one of these revealed a neurofibroma. He was treated with corticosteroids. Over the next six months he had a persistent slow gastro-intestinal blood loss, requiring 26 units of blood and two total dose iron infusions.

In December 1985 he returned with a severe melaena, and his haemoglobin was 4.3 g/dl. Shortly after admission a tin colloid radionuclide study and a superior mesenteric angiogram were normal. He was discharged from hospital well only to be readmitted later in the month with a further melaena. On this occasion a superior mesenteric angiogram showed active bleeding probably from the jejunum, but the precise site remained uncertain. He settled down on blood transfusions but a few days later developed abdominal pain, vomiting and signs of a perforated viscus.

At laparotomy he was found to have extensive involvement of the small bowel with multiple tumours (Figure 1), extending from 15 cm distal to the duodeno-jejunal flexure to 5 cm from the ileocaecal valve and one of these had perforated. There was no evidence of Crohn's disease. Sixty centi-

metres of jejunum was resected and following this he had an unremarkable post-operative course.

Examination of the resected jejunum revealed that the site of perforation was through an infarcted jejunal tumour (Figure 2). Histology revealed multiple intramural and submucosal smooth muscle tumours (Figures 3, 4). There was no evidence of malignancy.

Nine months after surgery he remained extremely well and maintained a haemoglobin 13.3 g/dl off iron.

Discussion

The frequency of involvement of the gastro-

intestinal tract in neurofibromatosis varies from 12–25%,^{1,2} but only a small number of patients have symptoms. The jejunum and stomach are the most frequent sites³ and the lesions are usually neurofibromas. Smooth muscle tumours, previously called leiomyomas and histologically indistinguishable from neurilemmomas^{4,5} are one of the commoner small bowel neoplasms but are very rare in neurofibromatosis. Up to 1986 only 14 cases of smooth muscle tumours of the small bowel in patients with neurofibromatosis had been reported in English language publications.^{3,6–12} That they occur in what was formerly thought to be neuroectodermal dysplasia may be explained by the current concept of neurofibromatosis as a generalised hamartomatous dysplasia.⁵

Symptoms caused by small bowel tumours depend on the position in the gastrointestinal wall – submucosal and intramuscular lesions can ulcerate, intussuscept, obstruct or perforate while subserosal lesions may cause no symptoms. Small bowel

tumours in patients with neurofibromatosis may also present with occult or torrential gastrointestinal bleeding.¹⁰ Bell has described a patient with a retroperitoneal neurofibrosarcoma which caused chronic intermittent blood loss over 21 years by invasion of the bowel.¹³

This patient had a 15 year history of chronic gastro-intestinal blood loss. There was no family history of neurofibromatosis and the diagnosis of neurofibromatosis was made only late in his clinical course. Chronic unexplained gastro-intestinal blood loss should prompt a search for cutaneous signs of neurofibromatosis.
