Summary: Discitis and vertebral collapse are rare but serious complications of lumbar puncture. Clinical profile, management and course of post lumbar puncture discitis in five patients is presented. Such a complication should be kept in mind whenever any invasive procedure is carried out on the spine.

Introduction

In modern day hospital practice, there are a number of indications that warrant access to the spinal subarachnoid space. Barring venepuncture, lumbar puncture (LP) is probably the most common invasive procedure undertaken. The side effects of LP are few: mild headache, which responds to analgesics and increased fluid intake, is the commonest. Serious complications include meningitis, and rarely discitis and vertebral collapse.¹ We present five patients with post-LP discitis, one of whom had vertebral collapse. The relevant literature is reviewed.

Clinical material

There were five patients with post-LP discitis seen in our hospital over a period of 7 years. Two of these patients developed discitis after LP in our hospital and three were referred from other hospitals. All patients were males in their third to fifth decades. The indications of LP, problems encountered during puncture, incubation period and radiological findings are given in Table I. Clinical profile of all five patients was similar: severe backache, paraspinal muscle spasm, inability to raise leg straight, no neurological signs and elevated erythrocyte sedimentation rate. All five were managed with bed rest, antibiotics (cloxacillin/ampicillin and gentamicin) for 6 weeks. They were allowed out of bed after 6 weeks and were followed up as outpatients. They all became pain free between 6 and 12 months. Spine radiographs after 12 months showed fusion across the infected disc space with formation of lateral spurs.

Discussion

Damage to an intervertebral disc is always a possibility during LP. It is likely that a number of

mild backache cases after LP may have a spontaneously resolving condition.² The needle pierces the annulus, producing varying sized haematoma, especially if repeated attempts are made, eventually predisposing it to infection. Even though scrupulous sterile technique is employed in most lumbar punctures, occasionally organisms will be introduced into the above *locus minoris resistentiae*.³ Blankenstein *et al.*⁴ described in detail how the intervertebral disc is initially infected and bacteria are introduced into the disc space at the time of intervention. A disc space infection ensues and the organisms are almost always confined to the disc space where the disc elements undergo sequestration, liquefaction and eventual resorption, with interspace collapse. Confinement of the infection to the interspace is probably due to a combination of cartilaginous plate barrier and the rich vascularity of the vertebral body, which prevents its sequestration and destruction; a vertebral osteomyelitis may ensue when the cartilaginous plate is damaged.⁵ Such a situation may arise after multiple punctures have been made in two adjacent spaces.

Clinically, post-LP discitis is characterized by a typical presentation. About two weeks after LP, the patient develops severe low back pain. There is marked paravertebral muscle spasm, and, occasionally, fever. Physical examination is remarkable for one thing: the paucity of neurological signs in the face of extreme pain suffered by the patient. Straight leg raising may be markedly reduced or cannot be tested.

Laboratory findings in these patients tend to be within normal limits, with the exception of raised ESR. Radiological changes may appear within 2–6 weeks. There is haziness or blurring of epiphyseal plates adjacent to the disc space. Destruction of the disc and that of the vertebral body can be seen clearly by computed tomography (CT) (Figures 1 and 2). The most effective early demonstration of suspected spondylodiscitis before any changes are visible radiographically⁶ is by magnetic resonance imaging.

Table I Discitis following lumbar puncture in five patients

Patient no.	Indication for LP	Remarks	Incubation period	Investigation	Radiological findings
1	Spinal analgesia	Repeated punctures at two spaces	2 weeks	X-ray, CT	Discitis L2/L3, L3/L4 with collapse L3
2	Spinal analgesia	Repeated punctures	6 weeks	X-ray	Discitis L3/L4
3	Spinal analgesia	Repeated punctures	4 weeks	X-ray	Discitis L3/L4
4	Diagnostic	Single puncture	3 weeks	X-ray, CT	Discitis L4/L5
5	Cranial CSF fistula	Twice daily puncture for 5 days	3 months	X-ray, CT	Discitis L3/L4

LP = lumbar puncture; CSF = cerebrospinal fluid; CT = computed tomography.

Figure 1 CT showing discitis L2/L3 (arrow).

Figure 2 CT showing L3 vertebral body destruction (arrow).

There is convincing evidence that the changes of discitis are the result of an infective process.⁷ Only a small number of bacteria are necessary to produce this complication and within weeks of it being established, the causal organisms cannot be isolated.⁷ In both the experimental animal and material obtained at autopsy, the histological picture is that of a chronic inflammatory process.⁸ The course of post-LP discitis appears to be similar to that of post-discectomy disc space infection. As time progresses, the disc space becomes markedly reduced and vertebral plates become indistinct. The space may disappear and healing begins with new bone formation in the form of sclerotic vertebral margins and spurs. In most

patients, healing and new bone formation leads to bony fusion. The process from active destruction to fusion takes anywhere from 6 months to 2 years. Management of post-LP discitis includes bed rest, analgesics and antibiotics for a period of 6 weeks. Generally a combination of semisynthetic penicillin and aminoglycoside is preferred. Our patients were relatively pain free and ambulant after 6 weeks. We do not recommend use of a rigid spinal brace. The sequence reported in these patients with one proceeding to bony destruction is rare; nonetheless such a complication should be borne in mind whenever any invasive procedure is carried out on the spine or its contents.
