THE SYMPATHETIC NERVOUS SYSTEM IN OBSTETRIC AND GYNAECOLOGICAL PRACTICE

By Albert Davis, M.D., Ch.M., F.R.C.S., M.R.C.O.G.

Gynaecological Surgeon, Prince of Wales', French, Dulwich and St. Giles' Hospitals, London

The fact that some degree of pain is accepted by most women as the normal, or periodic, accom-
paniment of their reproductive life is reflected in
the complacency with which their medical advisers,
both male and female, accept disabilities in women
which in male patients would demand immediate
attention. As a result an enormous amount of pre-
ventable pain is borne by these long-suffering
subjects, not because it is incurable but because it
is regarded as inevitable. In recent years, however,
considerable attention has been directed to the
possibility of alleviating this type of pain, and the
demand has stimulated considerable amount of
research into the influence of the autonomic nerve-
supply of the genitalia on both their sensory and
motor functions. This has resulted in the clarifica-
tion of many hitherto unexplained phenomena and
in the elaboration of several methods of neuro-
logical interference, both minor and major, in the
attempt to interrupt pain-producing impulses or
pain pathways. The purpose of this paper is to
summarize these anatomical and physiological
data, to correlate them with pathological observa-
tion and to indicate where their application to
treatment might be of value in clinical practice.

Anatomy and Physiology

The uterus receives sympathetic nerves from the
abdominal system and parasympathetics from the
nervi erigentes. The abdominal fibres originate in
the coeliac plexus, a complex mass of fibres and
ganglia arising from the confluence of the vagus
and splanchnic nerves and surrounding the
celiac axis. From here strong fibres run down-
wards on either side of the aorta, becoming re-
fined from the renal plexuses to form the inter-
mesenteric nerves. At the level of the bifurcation
of the aorta these nerves fuse to form the superior
hypogastric plexus, a bundle of several strong
intercommunicating filaments better known as the
presacral nerve. After receiving branches from
the lumbar ganglionated trunk the presacral nerve
passes downwards over the fifth lumbar vertebral
body and the promontory of the sacrum, below
which it bends sharply backwards into the pelvis
and almost immediately divides into the inferior
hypogastric plexuses. These are two flat bundles
of considerable length, each running at first down-
wards, outwards and backwards along the lateral
pelvic wall, behind the internal iliac vessels just
lateral to the side of the rectum and medial to the
levator ani and sacral plexus. Each then enters the
corresponding sacro-uterine fold, and runs for-
wards in it to join the nervi erigentes and form the
pelvic plexus.

The nervi erigentes carry the parasympathetic
supply to the uterus. They are long, fine branches
arising from the anterior divisions of the middle
three sacral nerves, from which they run forwards
and outwards in the sacro-uterine folds, at the
anterior end of which they join the hypogastric
plexuses to form the great pelvic plexus or plexus
of Frankenhausner. This is a quadrilateral flat
mass of neuro-fibrous tissue lying by the side of
the ampulla of the rectum. It serves as a vehicle
for the admixture of the sympathetic and para-
sympathetic nerves which supply it, and which are
by its means distributed in their correct propor-
tion to the pelvic viscera. These receive bundles of
fibres from the front of the plexus, the individual
viscera being supplied by nerves which mainly
accompany the vessels to the particular organ in
their final distribution. In the uterus the nerves
form a widely meshed plexus at the side of the
body, just beneath the peritoneal coat; from here
they enter the muscularis at right angles to end in
the myometrium and the capillaries. In the cervix
an additional plexus is formed just beneath the
squamous epithelium of the tip. The discovery of
this plexus (Davis, 1933) has clarified certain pre-
viously unexplained clinical results, e.g. the relief
of dysmenorrhoea by cervical dilatation, the
mechanism of first stage labour pain, the cause of
some sudden deaths, etc. (see later).

Central connections. In the spinal column the
sympathetic efferent fibres lie in the intermedio-
lateral tract and the parasympathetics in the medio-
ventral. The efferents run just behind and medial
to the former. The central sympathetic nuclei lie
in the posterior part of the hypothalamus, and the
parasympathetic in its anterior portion (Beattie,
1932). The cortical centres probably lie in the
pre-motor area close to those described for the intestine by Sheehan (1934).

The ovary is supplied by the ovarian plexus, which arises from the renal and mesenteric ganglia. It consists of two or three long communicating nerves which course downwards along the ovarian artery to the hilum, from which short branches supply all the structures of the organ. The Graafian follicles are each surrounded by a cup-like meshwork, the clinical significance of which will be discussed later.

**Physiology.** The nerves of the uterus are not essential for normal parturition, which can occur after complete sympathetic denervation and also after transection of the spinal cord. In normal circumstances, however, there is no doubt that they play a considerable part in the control of uterine activity. The precise action of each constituent has not yet been elucidated, but it is fairly definite that the sympathetic contracts the circular and inhibits the longitudinal muscle, while the parasympathetic exerts the opposite effect, the actions being mutually synergistic. The former also controls vascular tone and in addition carries most of the pain-sensory fibres from the organ. The ovarian nerves have similar functions.

With regard to *sensation*, the endometrium is insensitive to the usual stimuli. It is true that curettage of the unanaesthetized uterus is occasionally painful, and that such sensitivity is abolished by the previous intra-uterine application of cocaine, but then the operation itself is a much exaggerated stimulus. One is inclined to suggest that the pain in these cases is due to the tearing of nerve-fibres as the endometrium is stripped up, rather than to a specific and wholly unphysiological sensibility.

The peritoneal surface shares the general insensibility of the visceral peritoneum elsewhere.

The myometrium is of course sensitive to certain stimuli, namely exaggerated dilatation or contraction. A bag placed in its cavity and forcibly distended causes acute pain of both types (due to tension and spasm). The contractions of labour and the pain of artificial dilatation of the cervix are clinical examples. The ovary, though insensitive to most stimuli, is like the testis, markedly sensitive to moderate pressure, and the pain produced in this manner is strikingly similar in the two organs.

**Clinical Application**

To illustrate the clinical application of these data it is convenient to consider how certain specific painful pelvic conditions are affected by interference, either pathological or operative, with these autonomic pathways.

**Dysmenorrhoea**

The pain of spasmodic dysmenorrhoea is due to excessive contraction of the myometrium, amounting literally to a spasm, with a resultant intra-uterine pressure of anything up to 180 mm. of mercury (Moir, 1934) and subsequent vascular occlusion. The pain may be muscular or vascular in origin, but in either case is of sympathetic origin.

The great majority of primary dysmenorrhoeae are adequately relieved by carefully supervised medical treatment, including physiotherapy, specific exercises, mild analgesics, etc., but some remain intractable to these measures. These react well to various forms of sympathetic denervation, particularly when the spasmodic element predominates.

The oldest and simplest procedure is dilatation of the cervix. This is a type of sympathectomy, for it owes its effect to rupture of the sympathetic plexus which surrounds the external os. Unless this is rapidly and adequately stretched, however, the plexus remains undamaged, accounting for many of the failures following the procedure. The relief commonly observed after parturition is due to the accompanying stretching and laceration which occurs in the majority of primigravidae. To be effective, therefore, the procedure must be carried out radically and the cervix torn sufficiently to accommodate a large bougie (it is euphemistic to talk of "dilatation" beyond No. 10 Hegar). In addition, a hollow pessary must be left in the cervical canal to prevent nerve regeneration. This somewhat barbarous procedure adds the possibility of chronic cervicitis for infection of the laceration is inevitable, and with the advent of less traumatic methods it should fall into desuetude.

**Alcohol injection.** The aim of this procedure (Davis, 1936) is to block all the uterine nerve-supply as it lies concentrated in the pelvic plexus. If the correct anatomical relations are borne in mind, the method is a relatively simple one and may be carried out under minimal intravenous anaesthesia. With the patient in the lithotomy position, the lateral fornix is exposed by opposite traction on the cervix, and the point of a long non-flexible needle inserted 1 cm. lateral to the cervix. It is then passed laterally and posteriorly at an angle of $45^\circ$ to both the horizontal and vertical planes for 1.5 cm., being guided to the side of the ampulla of the rectum by an internal finger. This is the situation of the pelvic plexus, and here 1 ml. of absolute alcohol is slowly injected, the needle point being kept constantly moving and aspirated intermittently to avoid intravascular injection. The same procedure is then carried out on the other side. As a reinforcement a further 1 ml. of alcohol is then injected into the lateral
parametrium just lateral to the supravaginal cervix, to catch any fibres which may have escaped the plexus block (Blos, 1929).

The results of this procedure are good. A follow-up of 61 personal cases showed a permanent cure-rate of 70 per cent., as against an estimated average of 20 per cent. from simple dilatation of the cervix. It is therefore the method of choice in those cases of primary spasmodic dysmenorrhoea which are resistant to ordinary medical measures.

Resection of the presacral nerve. In patients who remain unaffected by single or repeated alcohol injection the more radical operation of presacral sympathectomy, first described by Cotte in 1923, is indicated. Complete denervation of the uterus is unnecessary, for it is the abdominal sympathetic constituent alone which carries the contractile impulses, exaggeration of which is responsible for the spasm characteristic of dysmenorrhoea. These sympathetic fibres are concentrated in front of the fifth lumbar vertebra as the presacral nerve, and it is in this situation that they are most readily accessible to section.

Exposure of the nerve is readily attained through a short midline subumbilical incision. Good anaesthesia and the highest Trendelenberg position are essential. The intestines are packed upwards, and the sacral promontory identified. The nerve lies on the body of the fifth lumbar vertebra, in the space between the common iliac vessels. The peritoneum over this area is picked up, incised vertically for 4 cm. and held away laterally to expose the pre-lumbar space. The plexus is now usually easily seen coursing downwards in the middle line as a single or as several communicating nerves, but as it is often adherent to the posterior parietal peritoneum this should be denuded if there is any difficulty in identifying the nerves. It is also well to pick up any lateral fibres, accommodating the whole leash in an aerynism needle. A piece of nervous tissue 2 cm. in length is now excised, ligature being unnecessary as bleeding is minimal, and the peritoneum is repaired with a running suture.

The operation is a relatively simple one, and careful identification of the neighbouring vessels and ureter will eliminate any danger of serious injury. Naturally any coincident pelvic pathology will be dealt with at the same time.

The results of this operation are on the whole good, and in carefully selected cases one can practically guarantee at least adequate relief. Reports by Cannon (1937), Cannaday (1938), Greenhill (1942), Cotte (1947), and many others give a high percentage of cures. Of my own series of 86 cases, 67 are free from pain over periods varying from one to 16 years. The operation should not, however, be undertaken lightly, for it carries with it the risks associated with laparotomy, and though these may be minimal, they should not be hazardous until after the failure of minor procedures. That these are reasonably successful is shown by the fact that my cases represent only 4.8 per cent. of all patients attending with the single complaint of dysmenorrhoea.

Ovulalgia

A good many women complain of brief attacks of pain in one or other side of the lower abdomen about a week after menstruation ('mittelschmerz'). The attacks are synchronous with ovulation, as shown by checking with temperature charts and ovarian palpation. When colicky in type, the pain is probably due to tubal contractions which occur at this time. The tearing pain sometimes complained of is almost certainly due to irritation of the parietal peritoneum by the follicular fluid and blood liberated on rupture. Generally, however, the pain is described as of tension type, and in these cases it almost certainly results from pressure on the peri-follicular plexus by a distended follicle. It has been shown elsewhere (Davis, 1939) how these nerves clasp the follicle like a bowl, so that when the ovary becomes cystic through failure to rupture (sclero-cystic disease), chronic pain of a similar nature may result. This latter type may be exaggerated by the congestion of the period ('ovarian dysmenorrhoea,' Browne, 1939).

In the majority of cases the pain of ovulalgia may be ignored, but occasionally it is severe enough to warrant ovarian sympathectomy. This consists in simple excision and ligature of a portion of the infundibulo-pelvic ligament; separate dissection is tedious and unnecessary. The results are good in carefully selected cases, but the possibility that the denervation may interfere with maturation of the ovum in a subsequent pregnancy should always be borne in mind.

Malignant Neuralgia

The intractable pain of inoperable carcinoma of the uterus may be of either visceral or somatic origin. It is important to differentiate between the two clinically for the latter will obviously be unaffected by sympathetic block. Somatic pain is probably due to a posterior radiculitis (Todd, 1934) and may be referred to the area of peripheral distribution of any of the lumbar or sacral roots. It is a severe localized neuralgia, often associated with paresis and paraesthesia. The visceral pain is due to malignant infiltration or compression of the pelvic sympathetic plexus or its branches (Brucker and Mezinescu, 1903). This causes a severe
when the but presacral filtration, abdominal
July 1949  DAVIS: Sympathetic Nervous System in Obstetric and Gynaecological Practice

Vaginal alcohol injection is usually impracticable
in these cases on account of local malignant in-
filtration, but presacral neurectomy will relieve
purely visceral pain, and should be carried out
when the general condition of the patient is
sufficiently good. In debilitated subjects, and
where abdominal masses are present, the method
of choice is \textit{intrathecal alcohol injection}. This
procedure, introduced by Dogliotti (1931) and
popularized by Green (1936), is designed to
destroy the sympathetic pain-afferents entering
with the posterior roots. The technique is
simple, and consists in the injection of 0.5 ml. of
absolute alcohol without admixture into the fourth
lumbar interspace, the patient lying on the side
and slightly prone, and the head end of the table
depressed to an angle of 15 degrees. This position
is retained for an hour, and the same procedure
repeated after ten days for the opposite side. The
method has the advantages of simplicity and safety,
and can, if necessary, be carried out in the patient's
own bed. Greenhill (1947), who has an unrivalled
experience of the operation, produced complete
relief in more than half of his cases. Although the
writer's personal experience is not so satisfactory,
paralytic complications having occasionally fol-
lowed, there is no doubt of the general effica-
cy of this type of subarachnoid injection in many cases
of malignant neurexia.

Magnesium sulphate is an efficient neuro-
caustic which is less generally destructive, and
Bates and Judovitch (1942), have advocated its
substitution for alcohol in subarachnoid injections.
General experience (Bourne and Williams, 1945)
has so far been disappointing, but the field is a
promising one.

Todd (1937) and Kenny (1947), have used
\textit{etidural procaine analgesia} for the relief of
malignant neurexia with moderate success. The
technique is similar to that used in obstetrics, and
consists in the injection of 50 ml. of a 1.5 per cent.
solution of procaine in arachis oil into the sacral
canal. The method is often difficult and the pain
relief usually temporary, but repeated injection is
practicable in experienced hands, and undoubted-
ly has its application to some cases. The same
remarks apply to \textit{paravertebral procaine block},
originally introduced by Delliapiane and Badiano
(1927), and practised more recently by Jarvis
(1944) and others.

\textbf{General Displacements}

The lateral horizontal axis of rotation of the
uterus passes through the supravaginal cervix,
approximately at the level of the pelvic plexus.
The organ may therefore be anteverted or retro-
verted without exerting any undue nervous trac-
tion. This accords with the well-known clinical
fact that 'physiological' displacement in either of
these directions is normally painless. The pain of
pathological retroversion is, in the majority of
cases, the result not so much of the abnormal
position as of its original inflammatory cause ex-
cept in exaggerated cases where the cervix is
pushed so far forward as to exert undue tension on
the uterosacral ligaments. In \textit{prolapse}, however,
the uterine descent necessarily exerts considerable
tension on the plexus with the resultant referred
backache characteristic of the condition. In this
condition a distinction must be made between
simple cystocele and rectocele and true uterine
prolapse. The former displacements involve
merely a longitudinal traction on the long nerves
passing downwards in the loose tissue between the
vagina and the bladder or rectum; as a con-
sequence both conditions may be relatively
painless.

\textbf{Recto-vaginal Endometrioma}

The often intensely painful nature of this con-
dition is well known, although at first sight the
looseness of the cellular tissue between the vagina
and the rectum appears to negative any consider-
able nerve traction. This is indeed true of non-
infiltrating tumours and one has seen a huge
recto-vaginal dermoid which remained symptom-
less until it produced obstruction during labour.
The rapidly invasive tendency of an endometrioma,
however, soon involves the nerves contained in
the septum and instead of being pushed aside they are
infiltrated by and enclosed within the tumour.
The nerves in question are long fine filaments
descending from the inferior border of the pelvic
plexus. They are extremely numerous being
destined for the supply of more than two-thirds of
the vagina and rectum and microscopic section of
the retrovaginal septum reveals their astonishing
richness and complexity. Endometriomatous in-
volvement of this rich meshwork is in itself not
necessarily painful but the increased pressure
accompanying the periodic menstrual enlargement
of the tumour is responsible for the characteristic
severe vaginal and rectal neurexia.

Of similar aetiology is the so-called \textit{pelvic cry}.\footnote{The lateral horizontal axis of rotation of the uterus passes through the supravaginal cervix, approximately at the level of the pelvic plexus. The organ may therefore be anteverted or retroverted without exerting any undue nervous traction. This accords with the well-known clinical fact that 'physiological' displacement in either of these directions is normally painless. The pain of pathological retroversion is, in the majority of cases, the result not so much of the abnormal position as of its original inflammatory cause except in exaggerated cases where the cervix is pushed so far forward as to exert undue tension on the uterosacral ligaments. In \textit{prolapse}, however, the uterine descent necessarily exerts considerable tension on the plexus with the resultant referred backache characteristic of the condition. In this condition a distinction must be made between simple cystocele and rectocele and true uterine prolapse. The former displacements involve merely a longitudinal traction on the long nerves passing downwards in the loose tissue between the vagina and the bladder or rectum; as a consequence both conditions may be relatively painless.}

This is a reflex call of peculiar character which may be elicited by pressure in the pouch of Douglas in the lightly anaesthetized patient during an abdominal operation, or by similar pressure in the posterior fornix when making a pre-operative vaginal examination. It has variously been called \textit{Albertin's reflex} (after the surgeon who first described it), the \textit{Espanade reflex} (for the extraordinary reason that the Japanese actors housed in the Espanade during the Paris ex-

hition made a similar noise) and by other names, but the name 'pelvic cry' appears most appropriate. It is due, of course, to almost direct stimulation of the pelvic plexus which occupies each side of the base of the pouch and is only separated from the peritoneum by a small amount of cellular tissue.

A similar reflex is often produced by the separation of the upper part of the posterior vaginal mucosa during the performance of posterior colporrhaphy. It has been considered by some writers as identical with the 'rectal call' of anal dilatation but is really of quite different aetiology. As has been shown above, the nerves from the pelvic plexus destined for the vagina and rectum enter the former from behind and the latter from in front. They are concentrated, therefore, in the rectovaginal septum, particularly in its upper part, and it is the operative stimulation of this extremely rich nervous meshwork which causes the reflex laryngeal spasm.

Pericervicitis

The cervix, like the uterus, is normally insensitive to movement. Violent displacement of either organ during examination or coitus is, of course, uncomforable but actual pain is caused only if the movement is predominantly vertical, for the position of the pelvic plexus at the fixed junction protects its branches from traction except in this axis. In inflammatory diseases of the pericervical tissues, however, painful movement of the cervix may be a striking clinical phenomenon; it is also the cause of the severe dyspareunia often experienced by these patients. The underlying condition is an inflammatory infiltration in the lateral cervical parametrium and the uterosacral ligaments, resulting as a rule from endocervicitis, and the symptoms are rapidly relieved by paracervical alcohol injection when the acute phase has subsided.

Young's syndrome. James Young has recently drawn attention to the frequent association of iliac fossa pain with chronic cervicitis. Both are, of course, common gynaecological disorders but the fact that they may be aetiological connected has hitherto escaped observation. Clinically the syndrome manifests itself in chronic lower abdominal pain, dyspareunia and leucorrhoea, with no obvious pelvic pathology except cervicitis. The pain in the iliac fossa may be evoked by movement of the cervix which is itself often exquisitely tender. The pain is resistant to all the routine methods of treatment including major operative procedures, but it reacts immediately to procaine injection of the pelvic plexus. Young explains this phenomenon by suggesting that the hypogastric pain is a true visceral pain, the iliac fossa pain being referred from the cervix to the abdominal area of its peripheral parietal segmental representation, the iliac fossa. This application of the Head-Mackenzie theory of visceral sensibility to the cervix is at once ingenious and clinically satisfactory, and though exception may be taken on anatomical grounds to the implication that the cervical innervation is exclusively autonomic, there is no doubt that Young's hypothesis adequately explains many hitherto difficult cases.

Posterior Parametritis

In this condition, the clinical features of which I have called the 'posterior parametritis syndrome,' the lower part of the pelvic plexus and its adjacent nerves are involved in a diffuse lymphangitis as they lie within the uterosacral folds. The primary cause is a severe chronic cervicitis, and as a result of the constant inflammatory process the secondary neuritis is similarly constant. The patient thus complains of continuous low backache, aggravated by menstruation and coitus. The uterosacral ligaments are readily palpated from the vagina as hard, tender, projecting cords with the uterus pulled into anteversion by their secondary contracture. Many French authors, notably Molin (1929), believe the condition to be due to the unsatisified spasm of coitus interrupted, but though this practice may aggravate the disorder, there can be little doubt of its primary inflammatory origin. Novocaime injection of the utero-sacral ligaments is a satisfactory treatment for this syndrome. The method is a simple one and consists in the injection of 1 ml. of 2 per cent. novocaime into the most anterior identifiable extremity of each ligament. Anaesthesia is unnecessary and though the initial relief is often only temporary, the procedure is easily repeated. In intractable cases, absolute alcohol may be substituted, though here the total quantity used is halved, and the injection placed superficially and medially to avoid ureteric and uterine vessel damage.

Ectopic Gestation

The pain in unruptured tubal gestation is due to local tension on the circular submucous plexus caused by rapid enlargement within the lumen. It is continuous, fairly severe and neuralgic in character, with interspersed colic resulting from reflex tubal contraction.

When an ectopic gestation ruptures, the pain is equally characteristic. It occurs in attacks lasting from a few to several minutes and is 'tearing' in character. The early attacks are due to the initial projection of blood on to the sensitive peritoneum and later to involvement of fresh areas by bodily movements or further haemorrhage. The pain is precisely the same as that of perforated peptic
ulcer. Graaffian follicle haemorrhage or any other condition causing acute extravasation on to a hitherto normal peritoneal surface is referred to the area of peripheral distribution of the particular spinal segments affected. These vary considerably and although the pain is usually situated in the lower abdomen commencing in the iliac fossa of the affected side, it may extend considerably higher, and I recently saw a case in which the pain was so exclusively epigastric that a diagnosis of perforated gastric ulcer was made and acted upon by a general surgeon. The shoulder tip pain so often present is probably due to diaphragmatic irritation, both the phrenic nerve and the cutaneous nerves of the shoulder being derived from the third, fourth and fifth cervical segments.

Of additional interest is the manner in which in small haemorrhages, and in the early stages of larger ones, the pain is localized to the shoulder of the same side as the rupture. Schumann is sceptical of the accuracy of this fact, but with Rubin and others I have found it correct in the majority of cases.

It is important to remember that small haemorrhages into the tubal wall may closely simulate the pain of tubal rupture or tubal abortion, and in a patient operated upon recently under this diagnosis there was no free blood whatever, a distended but unruptured isthmic gestation being present. The pain in this case occurred in spasms, described as cutting in character, but there was no distension pain or colic. A further point is that the first symptom in many cases of ectopic gestation is the actual rupture, though close subsequent enquiry will often reveal the presence of some previous discomfort often so slight as to be almost unnoticeable. Variations in individual sensibility, together with differences in the rapidity of the tubal distention would appear to account for this discrepancy.

Labour Pains

The neurogenic basis of the pains of labour is somewhat complicated. The pain is actually felt in the uterus itself in only a small number of cases. In the majority it is referred to the peripheral area of distribution of the last two dorsal, the first lumbar and the middle three sacral nerves. It is thus felt mainly in the deeper parietes of the lumbar, sacral, inguinal and hypogastric regions, and is accompanied by definite modifications in cutaneous sensibility (hyperaesthesia, hyperalgesia). This reference is further proved by the fact that the subcutaneous novocaine injection of the appropriate areas often relieves the pain.

In spite of this, however, the peripheral cerebrospinal nerves involved are not themselves directly affected by pressure from the uterus, as has often been suggested. Such direct pressure is anatomically impossible, for the projection of the lumbar vertebrae effectively prevents simultaneous bilateral pressure on the nerves of the lumbar plexus, while the sacral plexus, as Aburel points out, is well protected by tautly stretched ligaments. One may therefore postulate a primary stimulation of the pelvic plexus from the myometrial nerve-endings which are themselves directly stimulated by the chemical accumulation of muscular hypercontraction, centripetal transmission taking place along the autonomic nerve-pathways described above and overflow in the spinal cord to the adjacent posterior root ganglia resulting in reference along the posterior roots to the peripheral areas of supply of the particular cerebrospinal nerves affected.

Phlegmasia Alba Dolens

Apart from the severe and often intractable pain associated with this condition, the permanent oedema and disability which so often follow give its appearance in the young parturient a particular significance. The pain and much of the subsequent vascular damage are due to arterial spasm, reflex from the acute venous thrombophlebitis. To counteract this Lerich (1934) carried out lumbar ganglionic block (the sympathetic being predominantly vasocostrictor). The technique consists in the injection of 5 cc. of a 1 per cent procaine hydrochloride solution into and around the lumbar sympathetic cord. With the patient lying horizontally and on the side, the needle is inserted at a point 3 cm. lateral to the spinous process, and passed until the transverse process is reached. It is then moved medially and passed a further 3 cm. along the lateral border of the vertebra where it reaches the ganglonated cord. The injection is made after preliminary aspiration. My own experience of this method is restricted and the results equivocal, but there is no doubt of the dramatic improvement when the injection is successful, the intense pain immediately disappearing, and the oedema rapidly diminishing.

Summary

An endeavour has been made to show that most types of pelvic pain in women have a relatively simple neurological basis. The pain may be due to direct traction on nerve trunks, to irritation of nerve endings or to malignant or inflammatory infiltration of nerve plexuses. The frequency with which microscopic abscesses are found in presacral nerves removed for intractable pelvic pain has been shown elsewhere (Davis, 1938). It is, of course, obvious that the prime factor in relieving pain is the removal or other treatment of any obvious gross pathology, but there remains a
considerable number of patients in whom clinical changes are not obvious. In these cases appropriate neurosurgery, from alcohol injection to section, is of considerable value. Such measures are held also to be a valuable adjunct to general pelvic surgery in the eradication of long-standing and previously intractable pain.
