INTRA-ALIMENTARY Drip FEEDING FOLLOWING PARTIAL GASTRECTOMY

By Maurice Lee, M.B., B.S., F.R.C.S.
Senior Surgeon Upton Hospital, Slough, and Visiting Consulting Surgeon Iver, Denham and Langley Hospital, Windsor Group, North West Metropolitan Region.

Following operation for partial gastrectomy it is usual for the patient to leave the operating table with a Ryle’s tube in the stomach and a needle in a vein, through which are given normal saline or glucose saline, and in some cases blood.

The dangers of giving post-operative intravenous fluids has been stressed over and over again in recent years. It is known that a patient can die from too much fluid administered into the venous circulation, one reason being that it is difficult to know clinically how much fluid is needed, and the amount given is therefore more or less guesswork.

In the past it was felt that to give fluids into the intestine following an operation for partial gastrectomy would be against all the principles of surgical practice. The opinion is held that following an abdominal operation the intestines are in a state of temporary ileus, and that to put fluid into a bowel in this state is harmful. However, the writer has observed constantly, whilst carrying out an anastomosis of the jejunum to the remaining portion of the stomach that the jejunum shows no evidence of ileus, but on the contrary an active peristalsis is present. This clinical impression was confirmed by passing small quantities of a dilute barium solution down the feeding tube on the day following operation, and the barium was seen to reach the lower ileum within four hours.

It was therefore considered that intra-alimentary drip feeding was the method of choice after partial gastrectomy, but that the method could be improved to avoid the risk of leaking at sutures or of gastric retention. A twin tube was devised which enabled post-operative gastrointestinal aspirations to accompany alimentary feeding at site beyond the anastomosis, where the operation was a Billroth I or Polya-type.

The tube itself (Fig. 1) consists of a two-way tube, the larger being a Ryle’s tube for the purposes of aspiration of the stomach if needed. The smaller tube, which is vulcanized to the Ryle’s tube, is roughly 3 mm. in diameter, or 4 English catheter gauge, and projects 8 in. beyond the end of the Ryle’s tube. Several perforations are made in the terminal 4 in., and it is used for feeding. The end of the Ryle’s tube remains in the gastric remnant, while the end of the other tube projects 8 in. beyond the anastomosis into the duodenum or jejunum, depending on the type of operation performed. This tube (Maurice Lee Two-way Tube) (Fig. 2) is fed into the stomach prior to operation through the nose in the usual manner, and while the resection is being performed it is manually guided into its permanent quarters at the time of constructing the anastomosis. The tube is opaque to X-rays and confirmation of its position can thus be ascertained by means of a straight X-ray if it should be needed.
As usual the patient has an intravenous drip put up during the anaesthetic. This is to be considered as part of the anaesthesia, as the fluid given this way is solely to combat any shock which may ensue during the operation, and in addition it allows the anaesthetist to give any drug which he wishes to use during the period of anaesthesia.

As soon as the operation is over and the anaesthetist no longer needs to give any more intravenous fluids, these are stopped and the drip apparatus is switched from the intravenous needle to the feeding member of the two-way tube. At the most two bottles of physiological saline will be given during the operation. Most often only one bottle is needed. After the intravenous administration is stopped, a mixture of $\frac{1}{2}$ oz. Casilan to one pint of tapwater is given into the intestine at the same speed at which the intravenous drip is administered. In this way a large amount of protein is fed to the patient in the immediate post-operative period—a time
when much nitrogen loss is taking place. In this manner as much as 60 g. of protein can be taken in by the patient in the first 24 hours. This is continued until about the end of the third day, when the tube is removed, and normal feeding is commenced. The Casilan requires careful strain- ing to prevent its blocking the tube.

There is little risk of overloading the circulation by giving fluids into the bowel. But there are other reasons for adopting this method, one being that there is not the risk of giving the patient a thrombosis or thrombo-phlebitis. Although this is rare in intravenous therapy into an arm vein, it does occur frequently when the needle is intro- duced into a leg vein. These thrombotic veins are often remain painful or tender for quite a time. Again there is no likelihood of the needle becoming blocked, or coming out of the vein unnoticed, both of which occurrences are common with intravenous administration unless there is constant supervision.

Sometimes after an anastomosis has been

carried out, the stoma becomes temporarily oedematous and swollen, so causing some retention of stomach contents behind it. The small feed tube going through the anastomosis safeguards against this temporary blockage.

Finally, electrolytes and potassium replacement are given from the commencement, to ensure against any deficiency of these which might lead to ileus.

It has been found that as much as 6 pints of fluid can be absorbed from the intestine in 24 hours by the use of an intra-alimentary drip. Usually, however, the amount of fluid administered is in the neighbourhood of 4 pints. That this fluid is absorbed is shown by the estimations which were carried out on the blood sodium, potassium and chlorides, both prior to operation and in the immediate post-operative period when the drip was being given into the intestine. The pre- and post-operative readings were indetical.

In the first gastrectomy in which the Twin-tube was tried only glucose saline was given into the intestine, and the writer was so impressed with the comfort of the patient, the lack of thirst and absence of any sign of dehydration, that it was decided to administer the mixture of Casilan in all subsequent gastrectomies, thus feeding the patient from the beginning with proteins, fluids and electrolytes into the intestine. There is no doubt whatsoever that this form of therapy has proved itself far superior to the intravenous method of therapy which is the usual practice.

Summary

Intra-alimentary drip feeding has been insti-

the outside the entrant's nom-de-plume; these envelopes will not be opened until after judging has been completed.

Closing date for entries each year will be July 31. The first award will be made in 1957. Entries must be addressed to:—The Chairman of the Awards Committee of Council, The College of General Practitioners, 54 Sloane Street, London, S.W.1. Prizewinners will be advised by post towards the end of October, and the results will be announced in the leading medical journals in November.
