RESPIRATORY FAILURE AND CARBON DIOXIDE NARCOSIS

By E. KEITH WESTLAKE, M.A., M.D., M.R.C.P.

Senior Medical Registrar, Middlesex Hospital

All physicians are familiar with the clinical and biochemical manifestations of cardiac and renal failure, but the syndrome of respiratory failure has gained recognition more slowly. The primary function of the lungs is to maintain a constant exchange of oxygen and carbon dioxide between the blood and air. This is achieved by intermittent flushing of the alveoli with inspired air and the continuous diffusion of oxygen and carbon dioxide across the alveolar membrane. In normal individuals, these processes maintain the mean carbon dioxide tension ($p\text{CO}_2$) in the alveoli at 40 ± 5 mm. Hg. and the oxygen tension ($p\text{O}_2$) at 100 ± 5 mm. Hg. *Respiratory failure* may be said to be present when there is inability or failure of the respiratory centre and neuro-muscular mechanism to prevent the alveolar $p\text{CO}_2$ rising above, and the alveolar $p\text{O}_2$ falling below their normal values. The level of alveolar $p\text{CO}_2$ is determined by two variables: (a) the rate of carbon dioxide production by the body i.e. the metabolic rate and (b) the adequacy of alveolar ventilation. If the metabolic rate remains constant, the alveolar $p\text{CO}_2$ will vary inversely with alveolar ventilation. If the latter is halved, the $p\text{CO}_2$ will rise to double its original level and vice-versa. Similarly, if the rate of carbon dioxide production is doubled, alveolar ventilation must increase to the same extent if the alveolar $p\text{CO}_2$ is to remain unchanged. Respiratory failure is therefore characterized by relative underventilation of the lung alveoli in relation to body metabolism.

When breathing air, alveolar hypoventilation inevitably causes hypoxaemia (arterial oxygen unsaturation) as well as hypercapnia (raised arterial $p\text{CO}_2$) since as the level of alveolar $p\text{CO}_2$ rises, the alveolar $p\text{O}_2$ falls. The relationship between the alveolar gas tensions can be appreciated from the equation derived by Fenn, Rahn and Otis (1946)* and depends on the respiratory quotient (R.Q.)

$$p\text{CO}_2(0.21 + \frac{0.79}{\text{R.Q.}}) = (B - 47) \times 0.21 - \text{alveolar } p\text{O}_2$$

and the prevailing barometric pressure (B). For example, when the respiratory quotient is 0.79 and the barometric pressure 760 mm., this equation simplifies to: $p\text{O}_2 = 150 - 1.21 \times \text{alveolar } p\text{CO}_2$. Thus at the normal alveolar $p\text{CO}_2$ of 40 mm., the corresponding $p\text{O}_2$ will be 102 mm., but if the alveolar $p\text{CO}_2$ rises to 80 mm., the alveolar $p\text{O}_2$ must fall to 53 mm. ($150 - 1.21 \times 80$). Capillary blood leaving the alveoli cannot have an oxygen tension higher than this figure and the oxygen saturation of arterial blood will therefore be reduced to about 80 per cent. with the appearance of central cyanosis.

When the alveolar $p\text{CO}_2$ is suddenly raised from 40 to 80 mm., the volume of carbon dioxide dissolved in the arterial plasma increases from 2.8 vols. per 100 ml. to 5.6 vols. with consequent fall in blood pH from 7.4 to 7.1. Renal compensation for this respiratory acidemia, with partial restoration of the arterial pH toward normal, is brought about over a period of days by increased tubular reabsorption of bicarbonate and the excretion of a highly acid urine (pH 4.6–4.8) containing increased amounts of ammonium and chloride ions. Thus the biochemical effect of respiratory failure is the combination of hypercapnia, hypoxaemia and acidemia.

Causes of Respiratory Failure

Respiratory failure may result from organic disease of the central nervous system (for example, encephalitis lethargica (Barach and Woodwell, 1921), bulbo-spinal poliomyelitis (Plum and Wolff, 1951), motor neurone disease (Feltman *et al.*, 1952), brain stem haemorrhage) or of the respiratory muscles (for example, dystrophism myotonia (Benaim and Worster-Drought, 1954), myasthenia gravis, dermatomyositis). In general medicine, respiratory failure is most commonly encountered in patients with long standing chest disease whose ventilatory capacity is grossly diminished e.g. in chronic bronchitis and emphysema (Baldwin *et al.*, 1949) and severe kyphoscoliosis (Fishman *et al.*, 1956). Patients who are

FIG. 1.—Respiratory failure precipitated by an acute chest infection in patients with chronic lung disease. Arterial oxygen saturation and carbon dioxide tension on admission with, and recovery from, an acute respiratory infection. Single points represent patients who died.

able to maintain a normal alveolar $p\text{CO}_2$ when well, frequently develop acute respiratory failure with severe hypoxaemia and hypercapnia when subjected to the stress of a respiratory infection (Westlake, 1954). This is illustrated in Fig. 1. In this diagram the arterial oxygen saturation and $p\text{CO}_2$ during the course of an acute respiratory infection have been plotted as oblique arrows. The six normal subjects i.e. those without previous respiratory symptoms (represented by black triangles) were all suffering from extensive lobar pneumonia and in five the $p\text{CO}_2$ on admission to hospital was lower than that on recovery. This may be taken as the normal response to an acute chest infection. In the 39 patients with a previous history of chest disease (chronic bronchitis, emphysema and cor pulmonale), the arterial $p\text{CO}_2$ on admission was higher than on recovery in 37. In many instances the initial levels of $p\text{CO}_2$ were 30 to 40 mm. higher than those on recovery. Other factors that may precipitate respiratory failure in patients with chronic chest disease are severe asthma (Schiller *et al.*, 1951; Sieker and Hickam, 1956), chest surgery (Björk and Engström, 1955) and the ill-advised administration of morphine and other drugs which depress the sensitivity of the respiratory centre (Roussak, 1951; Samuelsson, 1952; Wilson, Hoseth and Dempsey, 1954). In rare instances, chronic respiratory failure occurs in the absence of either pulmonary or neurological disease, usually in

association with gross obesity (Burwell *et al.*, 1956).

The Diagnosis of Respiratory Failure

Clinical recognition of alveolar hypoventilation may be difficult and the only certain method of diagnosis is the demonstration of a raised level of $p\text{CO}_2$. This is most conveniently achieved by analysis of arterial blood since the $p\text{CO}_2$ of alveolar air and arterial blood are virtually identical. With practice, samples of arterial blood can be readily obtained by puncture of the brachial artery under local analgesia. Direct determination of both $p\text{CO}_2$ and $p\text{O}_2$ in arterial blood can be made by the bubble equilibration technique devised by Riley. This method has been extensively used in respiratory research but is technically too difficult for routine use in a biochemical laboratory. However, arterial $p\text{CO}_2$ can be accurately estimated by an indirect method. Blood pH, $p\text{CO}_2$ and total plasma CO_2 content are related by the well-known Henderson-Hasselbalch equation. If any two of these variables are known, then the third can be calculated. Thus, rearranging the equation:

$$p\text{CO}_2 = \frac{\text{Total plasma } \text{CO}_2 \text{ content mM/L}}{0.03 \times (\text{antilog blood pH} - 6.09) + 1}$$

Total plasma CO_2 content is measured by the manometric method of Van Slyke and Neill (1924) and blood pH with a glass electrode and pH meter. Practical details for measuring blood pH at body temperature are to be found in the papers of Wilson (1951), Severinghaus, Stupfel and Bradley (1956) and Wynn and Ludbrook (1957).

The Clinical Manifestations of Respiratory Failure

The disturbances of blood gas tensions and in blood pH caused by respiratory failure have profound physiological effects on the brain, cerebral vessels, heart and lungs and are responsible for the appearance of certain characteristic signs and symptoms which may make a bed-side diagnosis of respiratory failure possible.

Mental disturbance in respiratory failure varies with its severity. In mild cases the patient may be euphoric or mildly confused. More severe degrees of hypoxaemia and hypercapnia cause progressive deterioration in mental function with visual and auditory hallucinations, delusions, stupor and finally coma. Although disturbed mental function is principally due to cerebral anoxia (Simpson, 1957), the effects of hypercapnia and acidaemia on the brain should not be neglected. The effect of breathing 100 per cent. oxygen shows that hypoxaemia is only one of the factors concerned since the patient in respiratory failure, although considerably improved, often

remains confused and disorientated despite full saturation of the arterial blood with oxygen. If mental disturbance were solely due to hypoxaemia, an immediate return to mental clarity would be expected. *Impaired memory* is usual during a period of respiratory failure, even in the absence of obvious mental disturbance. After recovery from an acute respiratory infection, careful enquiry will often reveal that the patient has complete amnesia (lasting days or even a week or two) for the early phase of his illness, although at the time, he may have appeared alert and rational. *Muscular twitching* is another common neurological manifestation of respiratory failure. It consists of coarse, irregular, jerky movements of the fingers, arms and facial muscles and, less frequently of the trunk and legs. Similar movements have been observed in normal subjects exposed to severe anoxia.

A low arterial pO_2 , high pCO_2 and low pH all cause dilatation of the cerebral and retinal vessels, the volume of blood within the skull is increased and in consequence the C.S.F. pressure rises. In 12 emphysematous patients studied during respiratory infections (Westlake and Kaye, 1954), the C.S.F. pressure was above the upper limit of normal (200 mm.) in ten, and in five subjects it was over 350 mm. The highest pressure recorded was 600 mm. *Raised intracranial pressure* due to respiratory failure is frequently associated with a severe throbbing type of *headache* and in a few patients, frank *papilloedema* appears, with measurable swelling of the nerve head, gross dilatation of the retinal veins and flame-shaped haemorrhages. Papilloedema as a complication of emphysema was first described by Cameron (1933), and although some authors have attributed the phenomenon to raised venous pressure (Beaumont and Hearn, 1948), the work of Simpson (1948) leaves no doubt that the primary cause is cerebral vasodilatation consequent to respiratory failure, although in some cases raised jugular venous pressure may be a contributory factor. The combination of mental disturbance, headache and papilloedema may lead to an erroneous diagnosis of cerebral tumour as in the cases reported by Meadows (1947) and Conn *et al.* (1957).

While respiratory failure causes cerebral vasodilatation, it has the opposite effect on the pulmonary arterioles and the pulmonary artery pressure rises (Whitaker, 1954). In patients with pre-existing hypertrophy of the right ventricle (cor pulmonale) the sudden increase in pulmonary artery pressure that occurs during acute respiratory infections frequently precipitates *heart failure* with dilatation of the right ventricle, the appearance of gallop rhythm (best heard over the xiphisternum), raised venous pressure and peripheral oedema

(Stone *et al.*, 1953; Fulton, 1953; Flint, 1954). The cardiac output is usually normal or even moderately raised (Ferrer *et al.*, 1950; Mounsey *et al.*, 1952) and this, together with the vasodilator effect of hypoxaemia and hypercapnia on the small vessels of the limbs, is responsible for the warm extremities and bounding pulse present during episodes of congestive failure—in contrast to congestive failure in mitral stenosis, hypertension or ischaemic heart disease where the cardiac output is low and the extremities cold. As might be expected, congestive failure is most likely to occur when respiratory failure is severe. From Fig. 1, it can be seen that of 11 patients with an arterial oxygen saturation below 55 per cent. and pCO_2 above 70 mm., signs of heart failure were absent in only three.

Many of the features of respiratory failure are illustrated by the following case history: A 63-year-old log sawyer was admitted to hospital on January 12, 1955. Apart from a chronic 'smoker's' cough with scanty mucoid sputum he had been in good health until 1943, when he had a severe attack of acute bronchitis. Since then he had been subject to repeated exacerbations of winter bronchitis with purulent sputum, headache and wheeziness. In 1951, he noticed moderate exertional dyspnoea but this was not severe enough to interfere with his work. On January 3, 1955, after walking home in a gale, he felt ill and retired to bed. Subsequently his sputum became purulent and he complained of anorexia, wheeziness, insomnia and severe throbbing headaches. On January 7, 1955, his practitioner prescribed a four-day course of aureomycin (0.25 g. six-hourly) but despite this he continued to deteriorate, and on January 9, 1955, was disorientated with rambling speech and hallucinations. On admission three days later he appeared critically ill. There was deep cyanosis of the lips and nail beds, the neck veins were engorged to the angle of the jaw and he was unable to give any coherent history. Examination of the fundi showed dilated, tortuous veins with some blurring of the disc margins but no retinal haemorrhages. Heart sounds were normal with a regular tachycardia, rate 100. Blood pressure 115/55. Mild sacral oedema was present. Respirations were shallow and rapid and on auscultation of the chest coarse rales were audible at both bases with generalized inspiratory and expiratory rhonchi. The resting ventilation was 6.25 litres per minute (respiratory rate $40 \times$ tidal air 156 ml.). Analysis of arterial blood confirmed the clinical diagnosis of severe respiratory failure: oxygen saturation 44 per cent. (pO_2 26 mm.), pCO_2 raised to 88 mm. (more than twice normal) and pH reduced to 7.24 (normal range 7.36–7.44). A chest radiograph showed considerable cardiac

FIG. 2.—Development of carbon dioxide narcosis during oxygen therapy.

enlargement but the lung fields were clear. Treatment with oxygen, antibiotics, bronchodilators, nikethamide and corticotrophin resulted in rapid recovery from respiratory failure and disappearance of the signs of right heart failure. Studies on recovery showed that the arterial blood was still mildly unsaturated (O_2 saturation 91.4 per cent.), but that the pCO_2 (44 mm.) and pH (7.42) had returned to normal. The resting ventilation was again 6.2 litres per minute but the larger tidal air (310 ml.) now provided adequate alveolar ventilation. He subsequently returned to work and has remained in good health.

Carbon Dioxide Narcosis

In respiratory failure, there is a shift in the control of pulmonary ventilation from the medullary respiratory centre to the peripheral chemoreceptors of the carotid and aortic bodies. With rising arterial pCO_2 , the respiratory centre becomes less and less sensitive to the stimulus of carbon dioxide (Scott, 1920; Tenney, 1954; Prime and Westlake, 1954; Fishman *et al.*, 1955) and ventilation is increasingly maintained by the stimulus of hypoxaemia acting via the carotid and aortic chemoreceptors. Breathing high concentrations of oxygen abolishes the anoxic stimulus to breathing with the inevitable consequence that alveolar and arterial pCO_2 levels are raised and arterial pH lowered still further. It is this phenomenon that is responsible for the development of carbon dioxide narcosis during oxygen

therapy (Barach, 1935; Donald, 1949; Comroe, Bahnson and Coates, 1950; Cohn, Carroll and Riley, 1954; Westlake, Simpson and Kaye, 1955; Sieker and Hickam, 1956). A typical example is illustrated in Fig. 2. The patient, a 62-year-old emphysematous man developed an acute pneumococcal bronchitis with moderately severe respiratory failure: oxygen saturation 64 per cent. (pO_2 38 mm.), pCO_2 72 mm. and pH. 7.26. On admission to hospital he was rational and orientated but within four hours of being placed in an oxygen tent he had lapsed into a semicomatose state with profuse sweating and coarse myoclonic jerking of the arms. Arterial blood showed that the pCO_2 had risen to 105 mm. with fall in pH to 7.13 (equivalent to the inhalation of 15 per cent. carbon dioxide by a normal subject). Over succeeding days, the arterial pH gradually returned toward normal values and the arterial pCO_2 fell to 90 mm. Myoclonic jerking ceased and the patient regained consciousness but remained unduly drowsy. Throughout the period of oxygen therapy, the arterial blood remained fully saturated with oxygen.

A broad correlation has been established between arterial pCO_2 , pH and mental state. Westlake, Simpson and Kaye (1955) found that mental disturbance was usually present when the arterial pH was less than 7.2 or the pCO_2 above 100 mm., and coma when the pH fell below 7.1 or the pCO_2 rose above 120 mm. Most patients were conscious and rational if the pH was above 7.3 or pCO_2 less than 80 mm. These observations have been substantially confirmed by Sieker and Hickam (1956). They observed that there was usually no significant abnormality in mental state if the pCO_2 was less than 90 mm. and the pH above 7.25. Semi-coma or coma were always observed when the pCO_2 rose above 130 mm. and pH fell below 7.14. In general, the critical level for loss of consciousness in carbon dioxide intoxication is at a pH of 7.1-7.14 and pCO_2 of 120-130 mm., although increased susceptibility to the narcotic action of carbon dioxide may be found in individual cases.

Motor phenomena are common during carbon dioxide intoxication. They usually consist of fine tremors of the fingers, arms and facial muscles (Waters, 1937), but severe clonic movements of the limbs and generalized convulsions have been observed (Sieker and Hickam, 1956). The C.S.F. pressure often rises (Davies and Mackinnon, 1949; Westlake and Kaye, 1954)—despite relief of anoxic cerebral vasodilatation—and papilloedema may make its first appearance during oxygen therapy. Carbon dioxide intoxication also causes tachycardia, sweating, skin vasodilatation and alterations in blood pressure. In the early stage the blood

pressure may rise, but more severe degrees of hypercapnia and acidaemia are usually associated with a profound fall in blood pressure. Prolonged narcosis frequently causes death from respiratory depression.

For the child with acidosis

... to maintain the blood sugar

When there is difficulty in digesting fats as the result of carbohydrate shortage, the effect of Lucozade, with its glucose content and its pleasant flavour, can be quite dramatic. In fact, wherever there is a poor appetite and little power to assimilate ordinary food, Lucozade will frequently prove irresistible and quickly strengthening.

Lucozade requires no preparation. It is a lightly carbonated glucose solution with an attractive golden colour and a pleasant citrous flavour. The liquid glucose content is 23.5% w/v or about 21 calories for each fluid ounce.

LUCOZADE
