The LD50 of diquat is only half of that of paraquat, but nevertheless, the occurrence of diarrhoea, and the persistence of the poison for such a long period in the patient's urine would suggest that a considerable amount of diquat had been swallowed, rather more perhaps than the quantities of paraquat involved in those cases which have been reported to date. One case of paraquat poisoning has already been reported with successful treatment by forced diuresis (Kerr *et al.*, 1968) so that it is not improbable that this form of treatment may have contributed materially to the outcome of our case. Steroids were not given since there is no strong evidence to support their effectiveness in these patients. Both peritoneal and haemodialysis have been suggested as methods of removing paraquat from the body, but in view of the evidence that this patient was excreting diquat in the urine and the ease with which he maintained such an enormous diuresis, it was decided to persist with this single form of treatment.

Acknowledgment

We are grateful to Mr Carson of the Forensic Science Laboratory, Belfast, who carried out the diquat estimations.

CLINICAL syndromes associated with immunoglobulin deficiency (hypogammaglobulinaemia) are being observed more and more often (Marie *et al.*, 1965; Andolfatto Zaglia & Gasparotto, 1966; Israel Asselain *et al.*, 1966). On the other hand, a selective deficit in a single immunoglobulin fraction (dissociated deficiency) is rarely found (Werner *et al.*, 1965; Leveque, 1965; Israel Asselain *et al.*, 1966).

Recently we have observed a young woman afflicted with repeated respiratory infections from the age of 6 months. Examination of the immunoglobulins showed an absence of IgA accompanied by a partial deficit in IgG and IgM. We believe the case merits mention not only for its rarity, but also because it affords a basis for consideration of the biological significance of the γ A-immunoglobulins.

Case report

F.B., 12 years of age. Family history: a maternal aunt was affected with pulmonary tuberculosis. The

parents and five siblings are healthy. The patient was breast-fed for 3 months and appeared to have had a normal psychosomatic development. Menstruation began several days after her first recovery in our Institute in October 1965.

From the first weeks of life the patient was affected with a persistent cough and at 9 months underwent her first of eleven subsequent hospitalizations for bronchopneumonia. After several months she was transferred to a sanatorium where she remained until 4 years of age, frequently suffering from highly febrile bouts of non-tuberculous bronchopneumonia. In the following years the same pattern recurred, with infections always exclusively involving the respiratory system. During these febrile bouts the sputum was frequently mucopurulent. Morning vomiting was common.

At 8 years of age the patient had a negative Mantoux reaction and a normal blood picture. At 9 years old, during one of her numerous hospitaliza-

tions, bronchoscopy and bronchography were carried out which showed the presence of bronchiectasis in the middle right lobe.

Subsequent hospitalization followed annually and the patient was admitted to our Institute for the first time on 30 October 1965 because of a chest infection. Her skin was pale. There was no clubbing. The submandibular and cervical lymph nodes were enlarged, pea-sized and not tender. The interorbital and right maxillary areas were tender. The oropharynx was slightly congested and the tonsils showed chronic inflammation. There was evidence of rhinitis and sinusitis. Movement and tactile fremitus were reduced at the bases, with crepitations on inspiration. The heart was not enlarged; there was an increased pulmonary second sound. The liver and spleen were slightly enlarged.

Investigations

Chest X-ray and tomography (November 1965) showed a triangular opacity in the right middle lobe bordered by the major fissure, and a triangular opacity in the left lower lobe (Fig. 1). Bronchography

FIG. 1. Radiography of the thorax. Triangular opacity corresponding to the right middle lobe.

showed crowding of the bronchi in the lingula with bronchiectasis there and in the left lower lobe and in the right middle and lower lobes.

Respiratory function tests: Marked reduction in vital capacity without an increase in residual air. Normal Tiffeneau index; ventilatory reserve within normal limits. The spirometric indices give evidence of a moderately severe ventilatory insufficiency of an obstructive type.

Sputum culture: Repeated tests showed the presence of Gram-negative organisms, negative for Koch bacillus. Sweat test: negative (Na 106 mEq/l, K 20 mEq/l, Cl 50 mEq/l).

Schwachman test: Negative, **Congo-red test:** Negative.

Skull X-rays: Paranasal sinuses of average development for the age; the right frontal sinus smaller than the other. Thickening of the mucosa of the maxillary sinuses more on the left where the antrum is almost completely filled.

Blood: Hb, 75%; PVC, 40.5%; RBC, 4,950,000 mm³; WBC, 10,670 mm³. Differential: neutrophils, 59%; basophils, 0%; eosinophils, 5%; lymphocytes, 30%; monocytes, 6%; ESR 8.5 (Katz index). Blood sugar: 90 mg/100 ml; BUN, 18 mg/100 ml. Serum bilirubin: 0.32 mg/100 ml (total-indirect). Serum flocculation: Takata, 70; MacLagan, 0.40; Kunkel, 0.60; WW, negative; ASOT, 166 U/ml. Intradermal tuberculin reaction (1:10,000 dilution): negative after 24 and 48 hr. Total protein, 5.6 g/100 ml;

FIG. 2. Electrophoresis on paper of the serum proteins. Almost total absence of the band corresponding to the γ -globulin fraction. Normal findings below.

TABLE 1. Serum protein values

	Prior to vaccine stimulus				After vaccine stimulus		
	9 November	20 November	18 December	12 January	31 March	24 April	7 May
Total	4.90	4.70	4.70	6.60	7.00	5.80	5.80
Albumin (%)	61.00	76.90	54.90	62.20	47.70	55.00	52.40
α_1 -Globulin	5.6	5.2	7.5	5.6	8.3	6.6	9.2
α_2 -Globulin	16.3	7.7	15.5	12.8	14.5	16.9	15.5
β -Globulin	14.5	9.3	18.8	13.8	16.6	16.3	16.6
γ -Globulin	2.6	1.9	3.3	5.6	12.9	5.2	6.4

albumin, 3.93 g; globulin, 1.68 g/100 ml. A/G ratio: 2.9 (albumin, 70%; α_1 -globulin, 2.6%; α_2 -globulin, 9.6%; β -globulin, 15.4% and γ -globulin, 2.4%) (paper electrophoresis, Fig. 2).

The serum protein response to anti-tetanus vaccine stimulus (two injections at an interval of 10 days was studied, with controls) (Table 1).

Immunoelectrophoresis: The γ A-globulin fraction was absent while the γ G and γ M fractions were lowered (Fig. 3).

Radial immunodiffusion (Fahey's method for quantitative determination): IgG, 210 mg; IgM, 45 mg and IgA, 20 mg/100 ml.

Serum immunoelectrophoresis on the parents and five siblings: one brother (15 years old) showed a modest reduction in IgA.

Immunofluorescence on tonsil sections treated with specific anti-sera: fluorescence within normal limits with anti-IgG serum, no fluorescence with anti-IgA serum.

FIG. 3. Immunoelectrophoresis. Diminution of the IgG and IgM fractions and absence of the IgA fractions.

FIG. 4. Immunoelectrophoresis with IgA and IgM antisera. Absence of the line of precipitation of IgA (top) and presence of slight precipitation bands of IgM (bottom).

Blood type: type O Rh positive, CcDdee Blood complement 33 U/ml. Indirect and direct Coombs' test, negative. Haemagglutination tests cold and warm, negative.

Discussion

There is no doubt that in this case a close relationship exists between the immunoglobulin deficiency and the repeated respiratory infection, as in other previously reported cases (Migueres *et al.*, 1965; Gugler & Barandum, 1966; Israel Asselain *et al.*, 1966; Pernod & Kermarec, 1966; Pernod *et al.*, 1966). It is also certain that the bronchiectasis arose secondarily since its appearance was observed first on the right and then on the left. The occurrence of symptoms only 6 months after birth suggests the pre-existence of an immunological deficit.

However, the lack of familial involvement is in favour of a sporadic congenital form, according to the classification of Petersen, Cooper & Good (1965).

Qualitative and quantitative studies on serum immunoglobulin as well as those of immunofluorescence carried out on tonsil sections have shown an absence of IgA accompanied by a partial deficit in IgG and IgM. Thus, the case falls within the class of the rare so-called 'dissociated deficiencies' of immunoglobulins, likewise called 'atypical hypogammaglobulinaemia'. Up until now the following types have been observed:

(1) Deficit in IgG and IgA with an increase in IgM (Good & Zack, 1956; Israel Asselain, Burtin & Chebat, 1960; Heremans, 1960).

(2) Deficit in IgA and IgM with normal IgG Heremans, 1960; Pena Guitian, Varela Bujan & Gomez Vidal, 1963; Berheim *et al.*, 1964; Marano *et al.*, 1966).

(3) Deficit in IgA alone (Rosen & Bougas, 1963; Crabbe & Heremans, 1967).

Leveque (1965) considers that the latter, even though it has been observed in numerous children affected with repeated infections, can not yet be elevated to the category of a well-defined syndrome. Lending support to this, Bachman (1965) and Rockey *et al.*, (1964) have found an absence of IgA in, respectively, one and two apparently normal subjects. Others, however, have discovered this immunological deficit in children with the ataxia-telangiectasia syndrome, and more recently, Crabbe & Heremans (1967) have reported three cases of steatorrhea with selective absence of IgA, believing that malabsorption in this syndrome can lead to an immunological disorder; however, no pathogenetic mechanism for this was suggested.

It is probable that the isolated absence of IgA can cause symptoms, especially when it is associated with a partial deficit in the other immunoglobulins, in particular that of IgG, as in this case. A more pro-

found and systematic study of patients with repeated infective manifestations, mainly of the respiratory or gastro-intestinal tracts, would provide a stronger basis for this hypothesis. A more exact evaluation would then be possible of the biological significance of the γ A-immunoglobulins, or, as they are called by Heremans, Crabbe & Mason (1966), since they are present in higher concentrations in exocrine secretions than in serum, the 'exocrine immunoglobulins'.

Our first observations as well as those of others seem to confirm the hypothesis that the γ A-immunoglobulins have a protective function on mucous membranes, especially those of the respiratory tract. The reasons why the selective deficit of IgA is associated with isolated manifestations in both the respiratory and digestive systems remain unknown.

Correspondence

Modern trends in leprosy

SIR—The statement in the paper by Jamison (*Postgrad. med. J.*, 1969, **45**, 409): 'To-day in the United Kingdom no official figures are published . . .' is incorrect, since from time to time such figures are published.

The latest figures were quoted in a ministerial reply to a question in the House of Commons on 27 November 1968, and quoted in *Leprosy Review*,

1969, **40**, 65, as follows:

'By the end of 1967, 196 patients were reported to have been cured out of a total of 732 notified since 1951. Of the 357 patients remaining on the register at the end of 1967, 196 were known to be quiescent, but treatment was continuing as a precaution against recurrence.'
