Summary
A single dose of 150 mg clindamycin was given to nine patients with terminal renal failure being treated by maintenance haemodialysis and the blood levels were measured. Four of these patients were studied during haemodialysis and five between haemodialyses. Clindamycin (150 mg) was also given orally to four normal subjects.

The mean serum half-life in the normal subjects was 2.15 hr. For the dialysis patients the mean serum half-life off dialysis was 1.58 hr while that on dialysis was 1.85 hr.

There is evidence that clindamycin is excreted normally in chronic renal failure and that blood levels are not affected by haemodialysis. Normal adult doses, 150–300 mg four times a day, can be given safely in patients with chronic renal failure.

Introduction
Clindamycin (7-chloro-7-deoxylincomycin) is an antibacterial agent active against many Gram-positive organisms (McGehee et al., 1968).

Patients treated by maintenance haemodialysis are known to be subject to Gram-positive infections, especially those caused by staphylococci. Coagulase-positive staphylococci have been reported as causing infections of the Scribner shunt or Brescia-Cimino fistula (Clunie, Martin and Nolan, 1967; Curtis et al., 1969; Levi, Robson and Rosenfeld, 1970). These infections may result in septicemia. Although drugs of the penicillin group remain the treatment of choice for staphylococcal infections, strains of staphylococci resistant both to penicillin and cloxacillin are being found increasingly. These organisms are often resistant also to drugs of the cephalosporin group. Any addition to the number of antistaphylococcal compounds available is welcome, particularly as a number of patients may be allergic to drugs of the penicillin group. It would be an advantage if such a compound was non-toxic and excreted by pathways other than the kidney so that normal adult dosage could be given.

The work of Cimino and Tierno (1969) has suggested that in patients with terminal renal failure, the serum half-life of clindamycin is greater than normal both during and between haemodialyses. This report prompted the present study to determine in more detail serum levels and serum half-life of clindamycin in patients with terminal renal failure, both during haemodialysis and between haemodialyses. At the same time data are given for four normal subjects.

Methods
Nine patients and four normal subjects were studied. The patients were dialysed twice weekly for a total of 28 hr using a standard Kiil dialyser with cuprophane membranes (PT 150). Four patients were given 150 mg of clindamycin orally just before dialysis started; five other patients were given 150 mg of the drug the day after a dialysis. Blood was collected from the nine patients just before the drug was given and at 45 min, 75 min, 2 hr, 4 hr and 6 hr intervals after administration of the drug. Four healthy male volunteers were given 150 mg of clindamycin 1 hr after breakfast and blood samples were taken at the same times as for the patients with renal failure.

All blood samples were collected in heparinized tubes, centrifuged immediately and stored at –30°C. Assays were carried out by the well-plate diffusion method, using Sarcina lutea ATCC 9341. Wherever possible a standard curve was prepared for each subject using his own pre-dose serum; otherwise the standard curve was prepared in 0.1 M, pH 7.9, phosphate buffer. The half-life of clindamycin was determined after analysis of the data by the method of least squares using a computer.

Results
Table 1 shows the ages and weights of the patients and normal subjects together with the plasma levels of clindamycin at the times stated. For all four patients on dialysis, peak levels ranging between 2.34 and 3.50 μg/ml were found at 45 min. By 6 hr, levels approaching the lowest limit of sensitivity of the assay method were found.

Similar peak levels were found in patients between dialyses (2.16–3.50 μg/ml). In three of these patients
Clindamycin in renal failure

The peak occurred at 45 min, in one patient at 75 min and in one patient 2 hr after ingesting the drug.

The peak values of the normal subjects were rather lower (1.55–2.32 μg/ml) and occurred rather later (at 45 min in one subject, 75 min in two subjects and at 2 hr in the fourth subject) than in the patients with renal failure.

The mean half-life of clindamycin in the patients while being dialysed was 1.85 hr (range 1.7–2.1 hr) and between dialyses was 1.58 hr (range 0.9–2.1 hr). The mean half-life for the normal subjects was 2.15 hr (range 1.9–2.4 hr).

Discussion

Wagner et al. (1968) reported that the half-life of clindamycin in normal subjects was 2.38 hr. This is close to our finding of 2.15 hr. In normal subjects only 10–12% of orally administered clindamycin is recovered in the urine (Wagner et al., 1968; McGee et al., 1968). The main pathway of excretion is extra-renal, probably being excreted mainly by the liver like lincomycin itself. It is to be expected, therefore, that the half-life of clindamycin is normal in patients with chronic renal failure. Our findings are in agreement with this suggestion. In contrast, Cimino and Tierno (1969) found that the half-life of clindamycin was prolonged in terminal renal failure to 3.36 hr. However, these authors studied blood levels after giving clindamycin every 6 hr for 48 hr. Some accumulation of the drug may have taken place, and delayed absorption may also have occurred, both factors prolonging the half-life.

We are in agreement with Cimino and Tierno (1969) that dialysis has no effect on the half-life of clindamycin. This finding is surprising in view of the fact that clindamycin is approximately only 60% bound to serum proteins and has a mol. wt. of only 461.

The serum levels achieved after a dose of 150 mg of clindamycin are well in excess of the reported MIC against many strains of Staphylococcus aureus (Meyers, Kaplan and Weinstein, 1969; Geddes et al., 1970; Phillips, 1971). This finding, together with the lack of toxicity of the drug, suggests that clindamycin should be a useful drug in the management of staphylococcal infections in patients on maintenance haemodialysis. Normal adult doses, 150–300 mg four times a day, can be used.

Acknowledgments

We are grateful to Mr D. Hossack of Upjohn Ltd, Crawley, Sussex, for doing the clindamycin assays and to Upjohn Ltd, for supplying the clindamycin capsules.
