Summary

Opsoclonus, with or without polymyoclonia, is a rare syndrome. We report a case associated with an ‘oat-cell’ carcinoma of the bronchus. There is only one previous similar case reported in the world literature.

Introduction

Opsoclonus, originally described by Orzechowski (1927), may be defined as continuous irregular, chaotic, conjugate eye movement in all directions (Smith and Walsh, 1960). Often, although not invariably, it occurs in conjunction with myoclonic movements affecting the head and limbs. The syndrome has been reported most frequently among infants and children (Smith and Walsh, 1960; Cogan, 1954; Marmon and Sandilands, 1947; Kinsbourne, 1962; Baringer, Sweeney and Winkler 1968; Dyken and Kolar, 1968; Kennedy and Tucker, 1962; Bolthauer, Deonna and Hirt, 1979) although these accounts and others do include a few adult cases (Bolthauer et al., 1979; McLean, 1970). The aetiology often remains uncertain although a viral infection has frequently been suggested when there has been a prodromal upper respiratory tract infection or minor febrile illness. Sometimes the cerebro-spinal fluid (CSF) has contained excessive lymphocytes. Serological evidence of infection has only been given in isolated cases; mumps virus (Baringer et al., 1968), St Louis encephalitis virus (Estrim, 1977) and psittacosis (Blue, Janeway and Stanley, 1971).

Solomon and Chutorian (1968) were the first to describe opsoclonus in association with an occult neuroblastoma of childhood and since then there have been many similar reports (Bolthauer et al., 1979) confirming this relationship. Although isolated cases have been reported in association with such diverse conditions as vertebro-basilar ischaemia (Bri-

loss. The neck was not stiff and Kernig’s sign was negative. She was afebrile and there were no abnormal signs on general examination.

Investigations

Blood count, erythrocyte sedimentation rate, urea, electrolytes, liver function, thyroid function, chest X-ray, skull X-ray and electroencephalogram were all normal. Serological tests for syphilis were negative and paired sera screening for common viral antibodies gave no evidence for infection. The visual evoked responses were unrecordable as fixation was impossible. The cerebrospinal fluid contained 7 lymphocytes/ml but the protein and sugar values were normal. Computed tomography (CT) of the brain revealed no abnormality.

Her abnormal eye movement and myoclonus failed to respond to a variety of drugs; prochlorperazine, cinnarizine, carbamazepine, sodium valproate, diazepam, primidone and finally prednisolone 60 mg per day for 13 days. She deteriorated with a declining level of awareness and a virtual cessation of speech. She became incontinent of urine and faeces. Three weeks after admission she developed signs to suggest a chest infection and this was confirmed by a chest X-ray which also demonstrated a left hilar mass for the first time. Fibroptic bronchoscopy revealed a fungating lesion in the left main bronchus and a biopsy showed this to be an oat-cell carcinoma. A few days later she died and regrettably permission for a post-mortem was refused.

Discussion

Opsoclonus is rare. Orzechowski (1927) in his original description suggested that the responsible lesion lay in the mid-brain. The few cases which have come to post-mortem have generally shown changes in the cerebellum, cerebellar nuclei or mesencephalon. Ross and Zeman (1967) found medullary astrocytic and microglial proliferation in the olivary and pontine nuclei together with diffuse neuronal loss of cerebellar Purkinje cells in their study of a patient with opsoclonus associated with carcinoma of the bronchus. The site of neurological damage in our patient remains speculative but the cerebrospinal fluid findings support an inflammatory process. We suggest the addition of opsoclonus with polymyoclonia to the extensive list of non-metastatic manifestations of bronchial cancer on the nervous system.
