Summary

Undiagnosed myocardial infarction of the right ventricle presented as Dressler's syndrome. Radioisotopic diagnostic procedures including first-pass and multigated acquisition nuclear angiography (MUGA) and thallium-201 perfusion studies enabled a retroactive diagnosis of myocardial infarction, showed it to be in the right ventricle, and clarified the aetiology of the unexplained fever and pleuropericarditis.

KEY WORDS: aortic incompetence, pleuropericarditis.

A diagnosis of Dressler's syndrome requires evidence of myocardial infarction, followed after a variable interval of time, by fever, pericarditis and pleuritis (Dressler, 1959; Dressler and Leavitt, 1960). Classically, the myocardial necrosis is located in the left ventricle and the diagnosis of myocardial infarction has already been established when pleuropericarditis and fever appear (Dressler, 1959; Dressler and Leavitt, 1960).

We report a patient with a right ventricular myocardial infarction (RVMI) complicated by Dressler's syndrome. RVMI, as is often the case, had remained undiagnosed. Unexplained fever and pleuropericarditis prompted the retroactive isotope proof of RVMI and confirmed the proposed diagnosis of Dressler's syndrome.

Case report

A 62-year-old Caucasian male was admitted for investigation of fever of 6-weeks duration. Eighteen years previously, he had been hospitalized because of acute myocardial ischaemia of the anterior wall of the left ventricle. During follow-up, hypertension of 180/100 mmHg was treated with chlorthalidone 50 mg every other day. Because of persistent anginal syndrome 5 years before the present admission, he underwent coronary arteriography which revealed a 50% occlusion of the left anterior descending coronary artery, and irregularity of the intima of the right coronary artery. Regional wall motion was normal in all aspects and the left ventricle global ejection fraction was 72% (lower limit for our laboratory is 55%). Since that time he was known to have a stable anginal syndrome which caused chest pain upon moderate physical exertion. He was also known to have mild aortic valve insufficiency. Three months before admission, he had angina occurring at rest and fever of 2 days duration without leukocytosis. Isoenzyme studies for evidence of myocardial necrosis were within normal limits. Electrocardiogram (ECG) showed a transient T-wave inversion in the III and AVF frontal plane leads. As no clear evidence was found for myocardial infarction and the fever subsided spontaneously, he was sent home.

Six weeks later the patient developed fever reaching 38.0°C accompanied by weakness and anorexia. He was treated with co-trimoxazole and ampicillin without clinical improvement. During the week before admission, the patient noted moderate pain-

less swelling of the lower legs. Physical examination revealed blood pressure 130/90 mmHg, and temperature 37.8°C. There were no signs of venous congestion in the neck whereas the liver was tender and there was pitting oedema of both lower limbs. ECG showed a sinus rhythm and negative T-waves in II, III and AVF. No pathological Q-waves or signs of pericarditis were present.

On the third day of hospitalization, a pericardial friction rub was detected over the left parasternal area.

Laboratory studies showed ESR (Westergren) 30 mm in the first hour, WBC $8 \times 10^9/l$ with a normal differential. Biochemistry, autoimmune serology and blood cultures were unrevealing. Chest X-ray showed mild enlargement of the heart shadow by the left ventricle. A pleural effusion was seen in the left costophrenic angle.

An echocardiography (M-mode) study showed a mild pericardial effusion estimated at 150 ml, an increased end diastolic dimension of the right ventricle, a slight delay in the movement of the septum and hypokinesia of the free wall of the right ventricle.

On admission, diuretic therapy with frusemide 40 mg/day was begun. Seven days later, when the diuretic was stopped, there was significant venous congestion of neck veins and an increasing oedema of the legs. No signs of left heart failure were found on physical examination and repeated chest X-rays.

Multigated acquisition nuclear angiography (MUGA) was performed 5 days after admission and again 5 weeks later. The results in both examinations and in all views showed the right ventricular ejection fraction to be significantly far below normal (18%: normal values in our laboratory are $52 \pm 7\%$).

Akinesia of the free wall and hypokinesia of the inferior wall were clearly demonstrated. The left ventricle, on the other hand, appeared in all examinations and views to be normal at rest, while on effort the ejection fraction dropped to 46% (the lower limit of normal is 55%), and hypokinesia of the inferior wall was demonstrated.

Fig. 1 illustrates the perimeter of both ventricles at end systole and end diastole. The perimetry of the right ventricle in systole remains almost unchanged from that in diastole. Thallium-201 perfusion studies showed normal accumulation of radioactive material throughout the left ventricle in contrast to the complete absence of perfusion of the right ventricle in all views under all conditions. Fig. 2 shows a left anterior oblique view of the heart during rest. The lack of right ventricular uptake in this figure is typical of the results obtained.

Treatment was initiated with aspirin—4 g daily. After 2 days of this regimen, the general condition of the patient improved, fever returned to normal, the pleural effusion resolved and the pericardial friction

FIG. 2. Thallium 201 perfusion study showing lack of right ventricular uptake (left anterior oblique view).

rub disappeared. Treatment was stopped after seven days and restarted 2 days later because of the recurrence of fever. At this stage, diuretic and salt-free diet therapy were added. Signs of congestive heart failure cleared. The patient continued to do well and was released from hospital in good condition 2 weeks later.

Discussion

Right ventricular myocardial infarctions can be easily missed (Cohn *et al.*, 1974). A larger number are found at autopsy than are suspected during life (Wartman and Hellerstein, 1948; Isner and Roberts,

1978). That the right ventricle can be the site of severe myocardial necrosis has only recently been recognized (Cohn *et al.*, 1974). Involvement usually coexists with left ventricle infarction but can be isolated (Wartman and Hellerstein, 1974; Isner and Roberts, 1978; Cohn, 1979). The clinical expression of RVMI depends on the degree of pump dysfunction due to the severity of ischaemia and infarction of the left ventricle, the pulmonary vascular resistance, the site and extent of the RVMI, the systolic movement of the septum and function of the tricuspid and mitral valve (Cohn, 1979; Lorell *et al.*, 1979; Wackers *et al.*, 1978). RVMI should be suspected when venous hypertension coexists with clear lung fields (Cohn *et al.*, 1974; Cohn, 1979). The routine 12 lead-electrocardiography adds little to the diagnosis of RVMI, as in most cases only the T-wave changes in the inferior wall are seen, and for diagnosis of RVMI right chest leads must be added. A high level of clinical suspicion and modern imaging techniques have revealed a greater incidence of RVMI than was previously appreciated (Wackers *et al.*, 1978; Sharpe *et al.*, 1978). In our patient, clinical symptoms and electrocardiographic findings did not lead to an immediate diagnosis of infarction. Only when diuretics were withheld did the venous distension in the neck make right ventricular dysfunction evident. The prolonged fever and subsequent pleuropericarditis remained unexplained until a diagnosis of a recent myocardial infarction was entertained.

MUGA study demonstrated the diminished systolic performance of the right ventricle and thallium-201 scintigraphy confirmed the diagnosis of right ventricular infarction, by showing lack of perfusion to the right ventricle. Technetium-99 pyrophosphate studies were not performed because of the long interval from the suspected infarction, and since it was shown to be of limited value in such cases in our laboratory (Zafirir *et al.*, 1982).

Dressler's syndrome is a common complication of myocardial infarction occurring between the third

and ninetieth day after the infarction (Dressler, 1959; Dressler and Leavitt, 1960). In our patient, the clinical picture of prolonged fever and signs of pleuropericarditis, which promptly responded to salicylate treatment, together with firm evidence of a recent RVMI, confirmed the diagnosis of Dressler's syndrome.

Dressler's syndrome should be considered seriously for cases of unexplained pleuropericarditis and should prompt a search for undiagnosed infarction, especially of the right ventricle which tends to escape clinical detection.
