Hospital Practice

Estimation of glomerular filtration rate from the serum creatinine concentration

Stephen A. Smith

Department of Medicine, Flinders Medical Centre, Bedford Park, South Australia

Summary: In patients with renal failure the dose of renally excreted drugs should be reduced in proportion with the degree of impairment of glomerular filtration: in this situation it is appropriate to measure the glomerular filtration rate in order to determine accurately the correct dose. However, as 24 hour urine based creatinine clearance measurements are time consuming and inaccurate, the parameter most often used to estimate renal function in clinical practice is the serum creatinine concentration. An isolated serum creatinine concentration is unsatisfactory for this purpose as it depends on creatinine production, which is related to muscle mass, as well as on renal elimination of creatinine.

A variety of formulae and nomograms have been devised to assist clinicians in predicting the glomerular filtration rate from a stable serum creatinine concentration and the patient’s sex, age and weight (or height). Although some of these formulae have been available for over 15 years, the majority of doctors cannot estimate accurately the glomerular filtration rate from these parameters.

It is proposed in this paper that biochemistry results computers should employ one of these formulae to calculate the glomerular filtration rate/70 kg, using the age and sex information provided on the request form, each time a serum creatinine concentration is reported. These formulae are invalid in several well defined clinical situations which could be briefly outlined on the report.

Introduction

An accurate estimate of renal function is a vital tool in the management of patients with renal disease or when prescribing potentially toxic drugs that are excreted by the kidney. For this purpose it has been traditionally appropriate to measure or to estimate the glomerular filtration rate. Twenty four hour creatinine clearance measurements can be used to estimate glomerular filtration rate but the technique is time consuming, inconvenient and frequently inaccurate.¹-²

Thus the parameter most often used to estimate renal function in clinical practice is the serum creatinine concentration. Unfortunately serum creatinine concentration, when considered in isolation, is unsatisfactory as it is not directly related to the glomerular filtration rate. Serum creatinine concentration depends upon the balance between the production of creatinine and its excretion by the kidneys. Creatinine production is largely determined by muscle mass, which in turn is related to age, sex and weight, and will vary from patient to patient. In addition serum creatinine concentration is related to glomerular filtration rate in a reciprocal fashion; when renal function is normal or only mildly impaired, small changes in serum creatinine concentration represent large changes in glomerular filtration rate. In patients with renal impairment, the dose of renally excreted drugs should be reduced in proportion with the reduction in glomerular filtration: in this situation it is necessary to measure or estimate the glomerular filtration rate in order to determine accurately the appropriate dose.

Most biochemistry laboratories produce normal ranges for their serum creatinine assay based upon the mean±2 standard deviations of the results obtained from a large, it is hoped, heterogeneous population. However, these normal ranges are only valid for those having a normal renal function, i.e. glomerular filtration. In order to determine accurately the appropriate dose, it is necessary to measure or estimate the glomerular filtration rate.
population. This leads to the erroneous belief that all patients with serum creatinine values within the normal range have normal renal function.

Thus clinicians will be misled greatly if they base their clinical assessment of a patient's renal function on the serum creatinine concentration without fully understanding the effects of muscle mass on this parameter.

Can clinicians accurately estimate renal function from the serum creatinine concentration?

The importance of this problem is illustrated by the results of a postal survey that I conducted in a large British teaching hospital. A questionnaire was sent to 128 doctors (both junior and senior), working in clinical, medical and surgical specialties, outlining details of the ages, sex, weights and serum creatinine concentrations of five hypothetical patients (Table I). The doctors were invited to estimate each patient's renal function, in terms of glomerular filtration rate, from these parameters. The correct answers were determined using an empirical formulae described by Hull et al.\(^3\) as follows:

\[
\text{GFR}_{\text{(m)}}/70\text{kg} = 88 \times \frac{(145 - \text{Age})}{\text{Cr}} - 3
\]

\[
\text{GFR}_{\text{(f)}}/70\text{kg} = 0.85(\text{GFR}_{\text{(m)}}/70\text{kg})
\]

where \(\text{GFR}_{\text{(m)}}\) was the glomerular filtration rate for men (ml/min), \(\text{GFR}_{\text{(f)}}\) was the glomerular filtration rate for women (ml/min) and \(\text{Cr}\) was the serum creatinine concentration (\(\mu\)mol/l).

Figure 1 shows individual estimates of glomerular filtration rate for each of the five patients. The most striking feature was the wide scatter of answers. The majority of doctors overestimated glomerular filtration rate in patients 1, 3, 4 and 5 by failing to account for increased age (patient 5), low weight (patient 4) and female sex (patients 1, 3 and 4). Most underestimated the glomerular filtration rate in patient 2 for the same reasons.

It appeared that many doctors had considerable difficulty in accurately interpreting the serum creatinine concentration. Whilst some of the estimates of glomerular filtration rate were reasonably close, many more were so inaccurate that prescription of appropriate doses of renally excreted drugs such as digoxin and aminoglycoside antibiotics by these doctors would be more a matter of chance than of judgement.

Using serum creatinine concentration to estimate glomerular filtration rate

Creatinine clearance, traditionally regarded as the best method for determining glomerular filtration rate in routine clinical practice, is imprecise and unpredictably inaccurate. Errors may arise because of active secretion of creatinine by renal tubules,\(^4,5\) inaccurate urine collection\(^6,7\) and fluctuations in serum creatinine throughout the day.\(^8,9\) Creatinine clearance measurements made using routine laboratory services and hospital outpatient facilities have coefficients of variation as high as 27%,\(^2\) whereas isolated serum creatinine concentrations have day to day coefficients of variation of approximately 7%.\(^10\)

The idea of using single serum creatinine concentrations to determine glomerular filtration rate is attractive as many of the problems inherent in the measurement of creatinine clearance are avoided. The main difficulty with using serum creatinine concentrations has been correcting for

the influence of muscle mass. One solution would be to produce separate series of reference ranges for men and women of different ages and weights. These reference ranges are not yet complete although some work has been published in this area.11-15

An alternative approach has been to devise formulae or nomograms that compensate for variations in creatinine production and allow prediction of glomerular filtration rate from a subject's age, sex and weight (or height) and a stable serum creatinine value. Several such formulae have been proposed over the last 15 years.3-16-24 They have all been derived empirically and then tested prospectively by comparing their results with creatinine clearance or other measures of glomerular filtration rate. The first clinical application of a formula in adults was described by Jelliffe20 in 1971. A formula is available for use in children, where sex is a less important determinant of muscle mass, relating height and serum creatinine to glomerular filtration rate.21 Over the last decade these formulae have been modified and improved. Most give reasonable results with correlation coefficients of greater than 0.9 when compared with other methods such as measurement of creatinine clearance.

The Hull formula,3 which was used to determine the answers in my questionnaire, is particularly useful because it is simple and it has been validated by comparison with creatinine clearance over the whole spectrum of renal function, from normal to severe impairment, in patients with wide ranges of age and weight. The results obtained with this formula compare favourably with those from earlier formulae.3

Recently there has been vigorous debate about the relative merits of using the serum creatinine concentration or formal creatinine clearance measurements to determine renal function. Strong arguments have been tendered both for2 and against25 scrapping the 24 hour urine technique. At present it seems reasonable that those who wish to should continue to use the urine collection technique. However it is important that they should also be aware of, and able to apply, the alternative serum creatinine methods.

Problems in the interpretation of serum creatinine concentration

It is important to realise that serum creatinine concentration cannot be used reliably to calculate glomerular filtration rate in conjunction with the Hull formula (or any of the other formulae or nomograms) in all patients. Errors will arise in several well defined clinical situations:

1. In acute renal failure26 when serum creatinine concentrations are rapidly changing (either upwards or downwards). Formulae are only valid when a 'steady state' exists. Although more complicated formulae which take account of changing serum creatinine have been devised,27 this effectively means that renal function should not have changed greatly over the previous 4 days. The same restrictions also apply to 24 hour urine creatinine clearance.

2. Within 8 hours of a meat-containing meal. Serum creatinine concentration changes throughout the day in subjects taking a meat-containing diet. Increases of up to 80% were seen following a test meal containing 300 g of cooked beef8 and 30% increases have been described following ordinary hospital meals.9 These studies were undertaken in subjects with normal renal function: the percentage change would become much smaller as the baseline serum creatinine increases in subjects with renal impairment. If meat is avoided the serum creatinine concentration remains relatively constant.28-30 Early morning creatinine concentrations are remarkably constant and are preferred when accurate prediction of renal function is important. As serum creatinine rises with more severe renal impairment, the significance of dietary meat diminishes.

3. Strenuous exercise may increase the serum creatinine concentration by 14%.31

4. In severe oedematous states when muscle mass cannot be predicted from body weight. The same may be true for grossly obese subjects and women during the later stages of pregnancy.

5. In patients with marked muscle wasting.32

6. In children where the influence of sex on muscle mass is less important. Alternative formulae are available for use in children.21

7. In patients with liver disease.3 The reasons for inaccuracy of these formulae in liver disease are uncertain although muscle wasting and oedema may play a part. In patients with marked jaundice bilirubin may interfere with the creatinine assay.33

8. In ketotic patients where serum creatinine concentration may be falsely elevated by interference with the creatinine assay.34

9. Drugs such as salicylate,35 one or both of the components of co-trimoxazole36 and cimetidine37 can inhibit tubular secretion of creatinine, increasing plasma creatinine concentration without any change in glomerular function.
Conclusion

Several formulae are now available which allow accurate prediction of glomerular filtration rate from a single serum creatinine concentration. These formulae can be applied in the majority of patients although they are invalid in a number of clearly defined clinical situations. It seems that despite the existence of these formulae most hospital doctors are unable to interpret serum creatinine values in terms of glomerular filtration rate.

It is probably unreasonable to expect all doctors to remember a formula and use it each time they receive a serum creatinine result. However, it should be possible for biochemical computer systems to use the age and sex information that is provided in most request forms, and to utilize one of the available formulae to calculate a patient's glomerular filtration rate/70 kg body weight each time a serum creatinine result is reported. The situations where these formulae may be invalid could be briefly outlined on the report.

Measurement of serum creatinine concentration is amongst the most commonly performed biochemical tests in hospital practice. It appears that much of the information about renal function that this test could provide has so far been unavailable to the majority of clinicians.
