Summary: Alveolar proteinosis is a relatively rare disease of unclear pathogenesis associated with opportunistic infections. Although nocardiosis is the most frequent one, only 22 cases have been reported previously and are reviewed here.

We present a patient with alveolar proteinosis with nocardiosis treated as an emergency with bilateral bronchopulmonary lavage and antibiotics. No previous cases of this association have been successfully managed in this way.

Introduction

Pulmonary alveolar proteinosis (PAP) is a rare disease characterized by the intra-alveolar accumulation of periodic acid-Schiff positive proteinaceous material rich in phospholipids.

The pathogenesis of this disease remains unclear, although superimposed infections by unusual pathogens typically occur, Nocardia asteroides being the most common one. As far as we know, only 22 cases of this association have been previously reported.

PAP usually has an indolent course. In the case we present, urgent bilateral bronchopulmonary lavage (BPL) was performed because of the rapid progression of the disease. This is the first case in which the PAP associated with nocardiosis has been managed with BPL.

Case report

The patient was a 37 year old bricklayer with a 3 month history of dyspnoea on exertion, cough with minimal production of mucoid sputum and loss of 10 kg in weight. One week before admission low-grade fever was noticed. He smoked a pack of cigarettes daily for 20 years. Examination revealed cyanosis, digital clubbing and basal crackles. The temperature was 37.8°C and the respirations were 26/minute. The haemoglobin was 20 g/dl, the white cell count was $19 \times 10^9/1$ and the lactic dehydrogenase was 764 IU/litre. Arterial blood on room air at rest revealed $Pao_2$ 6 kPa and $PaCO_2$ 3.5 kPa, and pH 7.43. X-ray films of the chest showed diffuse bilateral alveolar infiltrates which spared the costophrenic angles. Diagnostic fibreoptic bronchoscopy with segmental lavage was performed. Flocculent material with Gram-positive filaments identified as Nocardia asteroides was obtained. Whitish disseminated lesions with erythematous margins were seen throughout the bronchial mucosa. Histological examination showed a distorted mucosa with fragmented and devitalized nocardias in it. The diagnosis of PAP was confirmed by transbronchial biopsy.

During the first week of hospitalization the patient’s clinical and radiological situation (Figure 1) rapidly worsened. The $Pao_2$ on 100% oxygen was 6.2 kPa. The patient was started on intravenous cotrimoxazole and a therapeutic BPL was performed on the left lung following a previously described technique using saline buffered to pH 7.8. Three days later, the other lung was also lavaged. On the 15th hospital day, the patient was discharged almost symptom-free. Blood controls were normal and arterial blood disclosed that the $Pao_2$ was 66 mmHg (8.6 kPa), the $PaCO_2$ 38 mmHg (4.9 kPa) and the pH 7.40, while the patient was breathing room air. X-ray films also showed complete clearing of the infiltration. The patient remains asymptomatic after a year on cotrimoxazole 1920 mg twice daily.

Discussion

PAP has had a ‘classic’ association with Nocardia asteroides. Indeed, Preger²² reported that up to 10% of

cases of PAP were complicated by nocardiosis. Nevertheless, in the review of cases of nocardiosis by Palmer et al. only 2% of the patients had PAP. To date, 400–500 cases of PAP have been reported and we have found only 23 associated with nocardiosis, including our own (Table 1). Thus, from a pure statistical perspective PAP rarely underlies nocardiosis.

The average age of the patients was 40.8 years, range 22–58 years and the male-female ratio was 2.8:1. The presentation and diagnosis of PAP and nocardiosis was simultaneous in only 7 cases. Usually, symptoms of PAP developed insidiously for months or years and then, fever, chills or other infectious manifestations superven. When there was central nervous system (CNS) involvement, focal neurological features such as unilateral headache, seizures or hemiplegia were noted.

The morphological diagnosis of PAP was established by means of open lung biopsy in 14 cases. However, the diagnosis can be made safely by transbronchial lung biopsy and examination of the effluent material from selective bronchoalveolar lavage (BAL), as in our case. In one case only BAL was necessary; in 5 cases the diagnosis of PAP was made at necropsy, in one by transtorial biopsy and in the remaining one by lobectomy.

Nocardia species isolated were N. asteroides in 22 cases and N. brasiliensis in one. Pulmonary involvement was present in 19 cases and 6 of them had systemic lesions (skin, CNS, kidney or elbow). Pulmonary infection was predominant in the upper right lobe in 7 patients and was diffuse in the other 12. CNS involvement was involved in 6 cases, 4 of them as an apparent primary infection. The cases in which cerebral nocardiosis developed in persons without a pulmonary focus of infection are surprising: we can only assume that a small pulmonary focus went undiscovered.

Sputum Gram’s stain was unremarkable except for 2 cases and sputum culture established the diagnosis in 6 patients. In 4 patients bronchoscopy yielded a turbid fluid which grew Nocardia; in another case Nocardia was isolated from joint aspirate. The culture of the piece obtained at surgery yielded the microorganism in another case. In the cases with CNS involvement, the diagnosis was made by culturing the fluid obtained during brain abscess drainase. The remaining 7 patients were diagnosed as having nocardiosis at autopsy.

Only three patients were given corticosteroids before the diagnosis of nocardiosis was made. The relationship of steroid therapy, PAP and infection is not as important for nocardiosis as it may be for fungus infections. Pulmonary defence mechanisms in patients with PAP are altered, and in vitro studies have shown that alveolar macrophages in PAP are defective. González Rothi and Harris have recently confirmed that alveolar macrophages in PAP are dysfunctional and their finding of decreased phago-lysosome fusion may be related to the high incidence of uncommon infections in these patients. These observations support the hypothesis that in patients with PAP, locally produced ‘toxic’ substances may impair alveolar clearance and contribute to the pathogenesis of this disease and superinfections.

Of the 23 patients reviewed 11 died and 12 were reported to be alive. In only 4 of the dead patients was the diagnosis of nocardiosis previously known. The infection was treated with antibiotics in 20 cases.

PAP, pulmonary alveolar proteinosis; N, nocardiosis; OLB, open lung biopsy; CNS, central nervous system; BAL, bronchoalveolar lavage; BBPL, bilateral bronchopulmonary lavage; IK, potassium iodide; (?) not clearly specified in the original article.
Sulphonamides and cotrimoxazole were the most useful agents; only two patients treated with them died. Cotrimoxazole is probably the current treatment of choice for nocardiosis.18,20

PAP usually has an indolent course; spontaneous resolution has been reported in one third of the cases described.27 PAP has a good prognosis in the long run21,27,28 and usually is not a life-threatening disease. However, the severe cases generally need repeated BPL. PAP has not been treated with BPL in any case associated with nocardiosis. Only Harris et al.16 performed a localized lobar lavage in their case. Our patient, whose respiratory function rapidly deteriorated was successfully managed with both cotrimoxazole and bilateral BPL. We can suggest that when opportunistic infections in PAP lead to significant respiratory failure, BPL should be performed without delay.

Probably, the prompt diagnosis of PAP and repeated BPL have made superinfections almost nonexistent. Only 5 cases of PAP and nocardiosis have been reported during the last decade16-20 and in three recent large series of PAP no infection has been super-added.21,27,28 Nevertheless, careful microbiological research is mandatory for patients with PAP.
