REVIEW

Magnesium in stroke treatment

K W Muir

Magnesium is involved in multiple physiological processes that may be relevant to cerebral ischaemia, including antagonism of glutamate release, NMDA receptor blockade, calcium channel antagonism, and maintenance of cerebral blood flow. Systemically administered magnesium at doses that double physiological serum concentration significantly reduces infarct volume in animal models of stroke, with a window of up to six hours after onset and favourable dose-response characteristics when compared with previously tested neuroprotective agents. Small clinical trials have reported benefit, but results are not statistically significant in systematic review. A large ongoing trial (IMAGES) will report in 2003–4 and further trials are planned.

For 15 years, neuroprotective agents have promised to add to the limited therapeutic armamentarium for acute ischaemic stroke, but have as yet delivered nothing. Despite major reductions in infarct volume in animal models of focal cerebral ischaemia by drugs that embrace a multitude of mechanisms of action, a succession of clinical trials in acute stroke have failed to translate histological animal effects into clinical improvement. The bones of abandoned drug development programmes have been thoroughly picked over in a bid to find reasons for these failures, and a mixture of inadequate animal data, poorly established pharmacokinetics, dose limiting tolerability problems, and overoptimistic trial design have variously been proposed as culpable. Magnesium sulphate is currently undergoing clinical trials in acute stroke; will this be the compound to break the mould and finally confirm the neuroprotection hypothesis?

GENERAL PROPERTIES OF MAGNESIUM

Magnesium ions have a physiological role in multiple processes pertinent to ischaemia. In the brain, magnesium is predominantly complexed with adenosine triphosphate (ATP), and is an important cofactor in cellular energy metabolism and protein synthesis. Brain magnesium concentrations are regulated by active blood-brain barrier transport that maintains cerebrospinal fluid concentrations higher than those in serum (typically 1.1 mmol/l compared to 0.8 mmol/l). Cerebrospinal fluid magnesium concentration increases by 20%–25% after typical intravenous or intramuscular treatment regimens both in animals and in humans, and peaks around four hours after parenteral administration. Magnesium concentration is selectively increased in regions of pathology in animals, including focal ischaemia and seizures. Intracellular free magnesium concentrations increase in ischaemic stroke, presumably largely through dissociation from ATP.

Magnesium generally antagonises calcium in biological systems, for example relaxing vascular smooth muscle and inhibiting calcium mediated activation of intracellular enzymes. Therapeutic uses of magnesium principally include obstetric use to prevent seizures in pre-eclampsia/eclampsia, and use in cardiology to prevent dysrhythmias. Wider cardiological application as a possible cytoprotective agent in acute myocardial infarction was suggested by meta-analysis and a moderate sized trial, but seemingly refuted in a very large open study, the fourth international study of infarct survival (ISIS-4). The possible failure of ISIS-4 to test magnesium in a biologically relevant manner has led to continued debate and further trials in myocardial infarction.

Magnesium is an attractive therapeutic agent: it is inexpensive, widely available, and intravenous or intramuscular administration yields predictable serum concentrations. Therapeutic effects are observed in pre-eclampsia at serum concentrations 2–3 times physiological (1.6–2.4 mmol/l). Magnesium is normally excreted by the kidneys with a half life of four hours or less, and adverse effects generally arise only in patients with significant renal impairment or in situations of iatrogenic overdose. Overdose can be detected clinically by loss of deep tendon reflexes (occurring at concentrations of 3.5 mmol/l and greater), and administration of calcium gluconate generally avoids significant problems. In rare cases, where serum concentrations are 5 mmol/l or greater, more profound neuromuscular block may necessitate temporary ventilatory support. Since conduction is slowed throughout the heart, symptomatic bradyarrhythmias may arise in individuals with heart block, but if used correctly, the risk of this even in patients with acute myocardial infarction in ISIS-4 was only 0.3%. The reasonably wide therapeutic index for magnesium contrasts with many synthetic neuroprotective agents which have been associated with...
major central nervous system side effects including psycho- 
mimetic potential, sedation and hallucinations, as well as dose 
limiting cardiovascular effects. However, since magnesium is, in 
practice, likely to be prepared by local pharmacies, care 
must be taken over the chemistry. Confusion has arisen from 
these processes. Magnesium loss by weight rather than by using SI units, since 
magnesium sulphate exists either as a heptahydrated or 
anhydrous salt, with molecular weights of 246 and 120 
respectively, and there is therefore a risk that double or half of the 
intended dose may be prepared.

### POTENTIAL MECHANISMS OF ACTION

There are numerous possible modes of action for magnesium in 
protecting neurones and glia from ischaemic damage. Reduction of 
cerebral infarct volume by magnesium may be consequent to 
effects on cerebral blood flow, or primarily neuronal 
actions, or more probably through a combination of 
these effects.

After middle cerebral artery occlusion, a core region where 
flow falls below around 10 ml/100 g/min (corresponding 
to the end arterial middle cerebral artery supply) rapidly 
necroses. The surrounding region of ischaemia, where 
collateral flow supports blood flows of 10-20 ml/100 g/min 
is known as the ischaemic penumbra. The metabolic and 
neurochemical consequences of ischaemia set in chain a com-
plex range of processes that, unless interrupted by reperfusion 
or (at least experimentally) by neuroprotective drugs, will 
result in the death of the penumbra. These processes include 
permanent release of neurotransmitters, particularly glutamate, 
excessive activation of post-synaptic glutamate receptors 
(including the N-methyl-D-aspartate (NMDA) receptor), 
excessive sodium and calcium ion entry to cells via ligand 
and voltage gated channels, and activation of calcium dependent 
intracellular enzyme systems, that lead to free radical produc-
tion, membrane lipid breakdown, proteolysis, upregulation of 
specific genes, and the initiation of both apoptosis and an 
inflammatory response.

In experimental systems, magnesium antagonises many of 
these processes. Magnesium ions are antieccitotoxic through 
inhibition of ischaemia-induced glutamate release, and 
through antagonist properties at the NMDA receptor ion 
channel, where magnesium ions provide a physiological 
voltage dependent block. Magnesium antagonises calcium 
entry via voltage gated channels of all types, enhances 
mitochondrial buffering of excessive calcium, and may 
prevent depletion of ATP. Intracellular magnesium concen-
trations in experimental systems are sufficiently high to 
antagonise a number of voltage gated ion channels including 
calcium, sodium and potassium, all implicated in cerebral 
ischaemia. Despite doubts about brain penetrance by systemi-
cally administered magnesium based on its pharmacokinetics, 
animal evidence that intravenous, intramuscular, oral, or 
intraarterial magnesium ameliorates direct excitotoxic 
brain injury induced by injection of NMDA, prevents NMDA 
induced seizures, increases free brain magnesium after 
head trauma, modifies NMDA receptor binding characteristics, and supports a potential neuronal mech-
anism of action in ischaemia.

In addition to the neuronal effects, magnesium also has a 
number of vascular effects that may be pertinent, particularly 
antagonism of vasoconstrictive mediators (for example 
eendothelin-1), enhanced cerebral blood flow—
prolong bleeding time, but no clinical consequences of this have been 
noted, even in ISIS-4 where concomitant thrombolysis and 
aspirin were frequently used.

### ANIMAL MODELS

In vivo, magnesium ameliorates histological damage in mod-
els of global forebrain ischaemia, focal head injury, subarach-
oid haemorrhage, and spinal cord ischaemia. It improves 
behavioural or functional outcomes after head injury or spinal 
cord ischaemia, prevents seizures provoked by various 
chemical or electrical stimuli, and antagonises a range 
of vasoconstrictive mediators that may be relevant to focal 
brain ischaemia. In vitro, magnesium prevents axonal 
axonal injury.

The most relevant model for human stroke is temporary or 
permanent middle cerebral artery occlusion, usually in rats. 
Magnesium has been tested in different models, by different 
investigators, and in different laboratories. This diversity of 
models and laboratories was a key recommendation in 
research aimed at improving neuroprotective drug development.

Results are summarised in table 1. Magnesium sulphate 
consistently reduces cerebral infarct volume after middle cer-
bral artery occlusion, with evidence of a dose response 
effect, within readily achieved serum levels, and a prolonged 
time window of up to six hours after onset of ischaemia, which is highly favourable for a neuroprotective drug. Rat 
serum levels of 1.49 mmol/l after a 90 mg/kg intra-arterial 
dose are associated with up to 60% infarct volume reduction, 
and retain efficacy when administration is delayed for six 
hours after onset of ischaemia. The same dose has antieccitotoxic activity in a rat seizure model. Average infarct volume 
reductions in rats range from 25% to 61%. Hyperglycaemia in 
rodents given magnesium chloride attenuates neuroprotection, but this has not been reported in humans and has not been seen in animals given magnesium sulphate. There is evidence of improved functional outcome and reduced mortality in magnesium treated animals.

### HUMAN TRIALS

A systematic review of neuroprotective agents modulating 
glutamate action disclosed six randomised, controlled trials of 
magnesium in stroke, including 716 participants. Unfortunately, 
data are available for five trials of only 206 patients,

Magnesium in stroke treatment

Box 1: Key features of the IMAGES trial

- Time window <12 hours after stroke onset.
- Inclusions: stroke with limb weakness.
- Exclusions: coma, renal impairment, pregnancy.
- Placebo or intravenous magnesium sulphate: 16 mmol loading infusion, then 65 mmol over 24 hours.
- Central randomisation via minimisation algorithm to ensure balance of prognostic factors.
- Outcome data (Barthel index and modified Rankin scale) at 30 and 90 days.
- Primary outcome: proportion of patients dead or dependent at 90 days.
- 80% power to detect 5.5% absolute difference in death or dependence; also has 80% power to detect a 7% absolute difference in outcome for patients treated within six hours of stroke.
- Magnetic resonance imaging (MRI) substudy to detect 25% difference in proportion of patients with infarct expansion between pretreatment diffusion weighted MRI and 90 day T2 weighted MRI.

The results of these small trials are encouraging, and have informed the sample size calculations for a large ongoing trial, the Intravenous Magnesium Efficacy in Stroke (IMAGES) trial. IMAGES is a multicentre study involving over 130 centres worldwide, and has now recruited over 2200 participants within 12 hours of stroke onset. Results are expected in 2003. Key features of the IMAGES trial design are described in box 1.

Viewed from the perspective gained from a decade of failed neuroprotective studies in stroke, the design of IMAGES may be criticised. In particular, the time window of 12 hours after stroke onset must now be regarded as optimistic, despite both favourable animal data for magnesium compared with many other drugs, and trends toward benefit for another neuroprotective drug with extended time window, citicoline. However, the sample size planned for IMAGES is larger than for any other individual neuroprotective trial to date, and the a priori assumption of around one third of patients being treated within the first six hours has been exceeded. Academic levels of funding—investigators receive about 1%-2% of the amount provided by commercially sponsored acute stroke trials per patient entered in IMAGES—have necessitated the participation of many small stroke centres, and many countries not usually involved in acute stroke trials, with potentially greater generalisability of results. Co-administration of recombinant tissue plasminogen activator (rtPA) is allowed, and IMAGES may therefore provide useful data in an area hitherto not extensively studied. There are clear theoretical advantages in combination therapy, with the possibilities that neuroprotective drugs may extend tissue viability and enhance the benefit or extend the time window for thrombolysis, and conversely, that reperfusion may enhance drug delivery and benefit from the protection. Animal data support this view. A sub-study using magnetic resonance imaging (MRI) parameters to assess treatment effect (MR-IMAGES) aims to recruit 150 patients and again may provide further insight. MRI studies with other neuroprotective agents reinforce the belief that MRI lesion volume provides a viable biomarker for activity. Finally, the FAST-MAG trial should provide the most rigorous test of neuroprotection ever undertaken with its protocol for pre-hospital treatment.

CONCLUSIONS

Magnesium is a promising neuroprotective agent. The preclinical profile is superior to many previously investigated compounds, and is robust in the hands of different investigators. Clinical experience is extensive in other therapeutic areas and the pharmacokinetics and safety profile of magnesium are already widely known. Large academically funded clinical trials in acute ischaemic stroke are ongoing after favourable trends in small trials. The IMAGES trial and its MRI substudy are expected to report in 2003, and the FAST-MAG programme thereafter may provide the most rigorous test of any neuroprotective agent yet undertaken.

QUESTIONS (TRUE T/FALSE F); ANSWERS AT END OF REFERENCES

Q1. Concerning magnesium physiology:

A) Cerebrospinal fluid magnesium concentration is in equilibrium with that in serum

B) Brain magnesium is predominantly in the free, ionised form

C) Magnesium is excreted renally

D) Hypermagnesaemia is associated with slowed cardiac conduction

E) Depression of deep tendon reflexes occurs with hypermagnesaemia

Q2. Neuroprotective agents for stroke treatment:

A) Have a well established role

B) Are contraindicated in patients given rtPA

C) Are thought to prevent cell death in the infarct core

D) May limit expansion of lesions on MRI

E) Share a common mechanism of action

Q3. Possible neuroprotective actions of magnesium include:

A) Inhibition of glutamate release

B) L-type calcium channel block

C) NMDA receptor activation

D) Antiaggregatory effects on platelets

www.postgradmedj.com
Q4. Concerning magnesium in animal models of stroke:
(A) Infarct volume is reduced if treatment is delayed by up to six hours
(B) The chloride salt is less effective than the sulphate
(C) Hyperglycaemia may be induced
(D) Neuroprotection is evident only at doses that cause neuromuscular blockade
(E) Is only effective if the blood-brain barrier has broken down

Q5. Clinical trials of magnesium have demonstrated:
(A) Unequivocal benefit in acute myocardial infarction
(B) Superiority to other agents in prevention of eclamptic seizures
(C) Reduced risk of death or dependence after stroke
(D) Increased risk of bleeding
(E) Benefit in subarachnoid haemorrhage and head injury
