CASE REPORT

Haemoglobin Marseille-Long Island and interpretation of HbA1c: which HbA1c result is the “right answer”? 

C M Florkowski, T A Walmsley, S O Brennan, P M George

A woman was screened for diabetes using glycated haemoglobin (HbA1c). Vastly different results were obtained by high performance liquid chromatography (4.5%), immunoassay (2.9%), and affinity chromatography (4.2%) compared with the non-diabetic range of less than 6.4%. Mass spectral studies confirmed the presence of a haemoglobin variant, haemoglobin Marseille-Long Island which had confounded interpretation by all methods.

An asymptomatic 44 year old woman was screened for diabetes using glycated haemoglobin (HbA1c), an index of average glycaemia, during the preceding 1–3 months. Initial HbA1c analysis was undertaken by high performance liquid chromatography (HPLC) on the Bio Rad Variant (Bio Rad Laboratories Inc; California, USA) and gave a result of 45% (non-diabetic range up to 6.4%). This result was considered to be biologically implausible and HbA1c analysis was therefore undertaken by other analytical methods. HbA1c was therefore analysed by immunoassay on the DCA 2000 instrument (Bayer Diagnostics) and was 2.8%, which was considered to be implausibly low.

It was decided to arrange further HbA1c analysis by affinity chromatography on the Primus instrument (Primus Corporation, Kansas City, MO, USA) which gave a result of 4.6%. Haemoglobin was submitted to mass spectrometry (VG Platform; Micromass, UK) which confirmed the presence of a haemoglobin variant, identified as haemoglobin Marseille-Long Island (see fig 1) which had confounded interpretation of these analytical methods.

DISCUSSION

The initial HbA1c of 45% by HPLC is implausibly high, especially in an asymptomatic woman with a low probability of diabetes. This raised suspicion of a possible haemoglobin variant. Haemoglobin electrophoresis on cellulose acetate (pH 8.6) gave a normal pattern. This prompted the decision to undertake mass spectrometry studies of HbA1c.

Mass spectrometry excluded a HbA1c of 45% and confirmed that the subject was heterozygous for haemoglobin Marseille-Long Island. This variant, originally termed haemoglobin Marseille7 was originally described in a diabetic Maltese woman, and subsequently termed haemoglobin Long Island.7 Structural analysis revealed the presence of a methionyl residue extending the amino terminus of the β globin chain and a histidine to proline substitution at the second position in the β chain.7 This substitution of a positively charged amino acid with a neutral one results in a net loss of one positive charge.

Haemoglobin Marseille-Long Island therefore has lower affinity for the ion exchange resin and coelutes with the HbA1c peak resulting in an artefactually high reading.

The immunoassay method (DCA 2000) relies on the ability of a specific antibody to recognise glucose bound to the amino terminal amino acids of the β globin chain.8 In the present case, the β globin chains from haemoglobin Marseille-Long Island have an amino terminal that is modified in a way that does not permit recognition by the antibodies of the DCA 2000 assay. Given that the subject is heterozygous for this variant and that half the β chains are therefore normal, then arguably the “correct” answer might be obtained by doubling the DCA 2000 result. This would give a value of 5.8%, which is plausible.

Affinity chromatography relies on a fundamentally different analytical principle, namely a covalent interaction between cis-diol groups in the glycated haemoglobin molecule and boronate residues in the affinity resin. Results are usually adjusted to give HbA1c equivalents8 and this method is the one normally considered to be least affected by haemoglobin variants. The modification of the amino terminus of the β globin chain in haemoglobin Marseille-Long Island, in particular the methionyl extension means that the fraction that is technically HbA1c does not exist. The absence of glycation at this site results in a value that is artefactually low. In the absence of any other evidence, this result, which is biologically plausible might have been accepted as “correct” in the present case.

Abbreviations: HbA1c, glycated haemoglobin; HPLC, high performance liquid chromatography
None of the obtained results therefore gives the “right answer” for glycaemic status. As indicated above, doubling of the DCA 2000 result may be argued as giving the “right answer” for glycaemic status. As indicated above, doubling of the present case would have been misleading given that half of the β chains show methionyl extension. Other methods are not specific for HbA1c, although are traceable to the HPLC method (Biorex 70) that was used in the Diabetes Control and Complications Study, and gave higher values. Opponents of the International Federation of Clinical Chemistry position favour that HbA1c methodologies should be aligned to the method employed in the Diabetes Control and Complications Study trial. The debate continues.

Notwithstanding all of the above considerations, the predictive value of HbA1c for diabetes depends on the chosen cut off and is not usually recommended as a screening test."

**CALL FOR FILLERS**

The *Postgraduate Medical Journal* invites readers to contribute fillers for the journal. They can be on any topic likely to be of interest but we particularly welcome fillers on the following:

- Favourite books.
- Life defining moments or patients.
- Medical history.

Fillers, of around 250 words, can be emailed to the editor at pmj@btinternet.com for consideration.
