Epidemiology of gastric cancer in Japan

M Inoue, S Tsugane

Despite its decreasing trend in Japan, gastric cancer remains an important public health problem. Although the age standardised rates of gastric cancer have been declining for decades, the absolute numbers are increasing because of the rapid aging of the population. A large proportion of Japanese gastric cancers are detected at an early stage, with a better overall survival rate. As with Western developed countries, a change in the social environment such as reduced salt use and increased fresh vegetable and fruit intake as well as improvement of food storage may play an important part in the decline. Differences in Helicobacter pylori infection rates between generations presumably have contributed to the generation related variation in the declining trends. It is expected that most gastric cancers in Japan may be preventable by lifestyle modification such as salt reduction and increased fruit and vegetable intake, together with avoidance of smoking and countermeasures against H pylori infection so that the level now evident in Western developed countries can be reached.

Despite its decreasing trend over many decades, gastric cancer remains a major public health problem in the world. In this review, recent epidemiological findings on Japanese gastric cancer are discussed to provide an up to date perspective.

DESCRIPTIVE FEATURES

World trend
According to the world estimate of cancer incidence in the year 2002 by the International Agency for Research on Cancer,1 gastric cancer is still one of the most common cancers in the world, the fourth most commonly occurring cancer (9% of all cancers) after cancer of the lung, breast, and colorectum, and the second most common cancer related cause of death (10% of all cancer deaths) after lung cancer. In 2002, the incidence of gastric cancer was estimated at 934 000 cases, 63 300 patients who developed lung cancer with 63 300 patients who developed lung cancer.1 By sex, death from gastric cancer was overtaken by lung cancer in men and by colorectal cancer in women. The incidence, however, continues to be the highest among all cancers. The latest estimate shows a total of 104 000 cases of gastric cancer occurred in 1999 (20% of all cancers) followed by lung cancer with 63 300 patients who developed lung cancer.1 By sex, the incidence of gastric cancer continues to be the highest among men, while in women, it was overtaken by breast cancer. Although age standardised incidence and death rates have been declining for decades, the absolute number of cases of gastric cancer shows an increasing trend (fig 2). The inverse trend between the absolute numbers and age standardised rates is considered to be attributable to the rapid aging of the population. The trend towards a decline is more prominent in younger than in older age groups, and there is an increasing trend only among those aged 85 and over. The average age at death from gastric cancer has also shown an increase from 61 in 1950 to 73 in 2000.2 Improvement of diagnosis for elderly people and the increased age at diagnosis may play a part.

Studies on Japanese migrants show that the incidence in the offspring of Japanese migrants tends to approach that in their host countries, such artefacts. Japanese gastric cancer rate ranks the highest along with that in Korea (fig 1). The highest incidence rate is observed in Eastern Asia, Eastern Europe, and South America, and the lowest rates are in North America, Oceania, Northern Europe, South east Asia, and South Asia. It is known that gastric cancer as a whole is more common in men, the male to female ratio of the incidence ranging from 1.5 to 3, although this varies with the age group, values of greater than 1 only in middle aged and elderly groups.1 In addition, the proportion of the undifferentiated type, in other words, the diffuse type, of gastric cancer is higher among female or young patients than among men or elderly people.

In most countries, gastric cancer shows a constant declining trend.2 10 11 Even where gastric cancer occurs infrequently nowadays such as in the USA and Northern Europe, it was recognised in the past as one of the major cancers, and a dramatic reduction in the incidence of gastric cancer has occurred.

Time trend in Japan
In Japan, gastric cancer was ranked as the most common cancer in the past, but this aspect has gradually been changing in recent years. Japanese gastric cancer has been overtaken by lung cancers as the leading cause of cancer related death since 1999, then accounting for 16% (49 500 deaths) of all deaths from cancer that occurred in 2003.11 By sex, death from gastric cancer was overtaken by lung cancer in men and by colorectal cancer in women. The incidence, however, continues to be the highest among all cancers. The latest estimate shows a total of 104 000 cases of gastric cancer occurred in 1999 (20% of all cancers) followed by lung cancer with 63 300 patients who developed lung cancer.12 By sex, the incidence of gastric cancer continues to be the highest among men, while in women, it was overtaken by breast cancer.
with the degree of reduction dependent on the degree of Westernisation and the actual incidence rate in the respective host countries. In a comparison between Japanese migrants to the USA and Brazil, two major target countries for Japanese migration, Japanese migrants to the USA show a significantly lower incidence rate than Japanese living in Japan, while Japanese migrants to Brazil show a similar rate to the latter group. This suggests that the traditional Japanese dietary practice, retained among Japanese migrants to Brazil than those to the USA, contributes as a risk factor for this cancer.

**CLINICOEPIDEMIOLOGICAL FEATURES**

Japanese gastric cancers as a group show characteristic features. Firstly, the distal stomach is more frequent as the site of occurrence than the proximal portion. With clinico-pathological finding of surgical cases, around 80% of cases are located in the middle or lower thirds of the stomach. The proportion of the distal cancers increases when restricted to early gastric cancers detected at an early stage and to cases in the elderly population. Similar features are also corroborated by population based data, although such data are limited by a high proportion of cancers with an unknown location. About 15% of cancers seen in the Japanese registries are located in the upper portion of the stomach.

Secondly, although the prognosis for gastric cancer is generally poor, better survival rates are seen in Japanese patients. An international comparison, based on population based cancer registries in developing countries and Western developed countries, shows a five year relative survival rate of about 20%, while it is 40%–60% in Japan (fig 4). The comparatively good overall survival in Japan is considered to be attributable to the large proportion of gastric cancer diagnosed at an early stage in Japanese patients. In 1995–2000, 53% of Japanese gastric cancers were localised when diagnosed, which is comparatively high as compared with the 27% reported by the US SEER programme. A similar low rate of localisation is speculated to exist in other Western countries. In addition, a report from a population based registry has indicated that the overall five year survival rates for gastric cancer improved from 28% for cases diagnosed in 1975–77 to 50% for those after 1990–92. On the basis of the clinical extent, the survival rate for localised cases improved from 65% for those diagnosed in 1975–77 to 86% for those after 1981–83, while the respective figures for non-localised cases were 23% to 32%. No improvement was seen for cases with distant metastases. Thus, the increase in the proportion of cases detected at an early stage may have made a strong contribution to the improvement in overall survival. It has also been found that the survival rate increases in tandem with the increase in the proportion of gastroscopic examinees, but not with the increase in cases detected by screening. A recent report pointed out that in Japan, the group of localised cancer included intramucosal tumours, while such cases would not be included as gastric cancers in Western countries. This bias may influence the proportion of localised cancer and with survival.

advanced stage with time and that they led to death if left untreated.26

RISK FACTORS AND PREVENTION

A dramatic reduction in gastric cancer has occurred in Western developed countries over the past century. In these countries, no active primary and secondary prevention measures were introduced, instead, changes in the social environment, such as reduced salt use and increased fruit and fresh vegetable consumption associated with improved food storage with freezers and refrigerators are generally considered to have had important parts in the reduction of gastric cancer cases. These factors may also be applicable in Japan.27 According to the report of a joint WHO/FAO Expert Consultation in 2003, although insufficient evidence existed to grade dietary factors as either a “convincing” risk or protective factors, a high intake of salt preserved foods and salt and reduced fruit and vegetable intake were evaluated as a “probable” risk factor of gastric cancer.28 The association between smoking and gastric cancer is well established, and an evaluation from the International Agency for Research on Cancer concludes that smoking is one of the convincing risk factors for gastric cancer.29 Positive association with chronic atrophic gastritis, drinking habits, barbecued or grilled cooking and an inverse association with green tea are considered also to be possible modifying factors.30 In addition, Helicobacter pylori infection is considered as an important risk factor of gastric cancer. In Japanese asymptomatic populations, the prevalence of H pylori varies with age; with infection seen in less than 50% of subjects under the age of 30 as compared with an infection rate of as high as 70%–80% in those aged 50 and over.31–34 It has also been found that the H pylori positive rate increased at 1% per year for those born after 1950 but was high and comparatively constant for people with birth dates before 1950.35 The infection status in adults is considered to be influenced by the socioeconomic status in childhood. Given the massive improvement in hygiene and the economic environment in Japan in the postwar decades, differences in the infection rates between generations presumably have contributed to the variation in the declining trends in incidence and death rates of gastric cancer among Japanese when the cases are grouped according to their year of birth. On the other hand, considering the high prevalence even in the low gastric cancer rate areas of south east Asia,35 and that a small proportion of subjects with H pylori infection develop gastric cancer during their lifetime, to contribute to the risk of gastric cancer, infection with H pylori presumably must interact with other factors, including dietary habits, host factors, and virulence of the H pylori infection.

A mass screening programme with photofluorography for gastric cancer has been conducted in Japan since 1960. Over six million Japanese attend the screening annually, the participation rate being 10%–20% of the target population.36 Previous reports showed an acceptable accuracy of early detection with the screening programme and better prognosis for screen detected cancer cases.37 On the other hand, descriptive data show that the age standardised death rates declined almost in parallel with the incidence rate in the 1960s, while the gap between them became wider after the 1970s. As the rate of both incidence and death have been declining, it seems that the reduction in the rates is attributable mainly to changes in these environmental factors and the discrepancy between the incidence and death rates can be explained in part by efforts made to achieve early detection.37

FUTURE PROJECTION AND PERSPECTIVE

According to future projections, both age standardised incidence and death rates will consistently decrease, with a

Epidemiology of gastric cancer in Japan

1. Gastric cancer is increasing worldwide.
2. More than half of gastric cancer cases occur in Eastern Asia.
3. Changes in the social environment, such as reduced salt use and increased fruit and vegetable consumption through improved food storage with freezers and refrigerators is considered to have played a minor part in the reduction of gastric cancer cases in Western developed countries.
4. The prevalence of \textit{H pylori} infection and the incidence rate of gastric cancer are in direct proportion.
5. Mass screening is generally considered to have had an important part in the reduction of gastric cancer cases in Western developed countries.

Learning points
- For stomach cancer, more than half of the new cases are from Eastern Asia, with 41% from China and 11% from Japan.
- In most countries, gastric cancer shows a constant declining trend.
- Rather than active primary and secondary prevention measures, the important parts in the reduction of gastric cancer cases in Western developed countries are generally considered to have been played by changes in the social environment, such as reduced salt use and increased fruit and fresh vegetable consumption associated with improved food storage.
- \textit{H pylori} infection is considered as an important risk factor for gastric cancer, but \textit{H pylori} infection contributes to the risk of gastric cancer presumably by interacting with other factors, including dietary habits, host factors, and the virulence of the infection.
