Gas patterns on plain abdominal radiographs: a pictorial review

Rachel E Musson,1 Ian Bickle,1 Ram K P Vijay2

ABSTRACT
Abdominal radiographs are one of the most commonly performed radiological examinations and have an established role in the assessment of the acute abdomen. The main indication is for suspected bowel obstruction and in conjunction with an erect chest x-ray for suspected visceral perforation. Often, the pattern of gas points to a particular pathology, and accurate interpretation is important for prompt diagnosis. The diagnosis in most cases will be confirmed by further imaging studies such as ultrasound, contrast studies or, most commonly in contemporary practice, CT. This pictorial review summarises the various types of intraluminal and extraluminal gas patterns, illustrates some of the common clinical diagnoses made from plain films, describes some commonly encountered clinical problems with radiographs, and discusses the role of advanced imaging techniques.

INTRODUCTION
Abdominal radiographs have an important, well-established role in the initial evaluation of the acute abdomen in the emergency setting. It remains one of the most commonly requested investigations despite advances in other imaging modalities, such as ultrasound, CT and MRI, and regardless of the limited evidence supporting their use.

Although plain radiographs generally have a low diagnostic yield and the majority show a non-specific pattern of gas distribution, there are several patterns that may point towards a particular diagnosis and hence influence further management. The patterns distinctive of particular abnormalities are often subtle and may be overlooked if not considered when evaluating the plain radiograph.

Our aim in this pictorial review article is to describe the assessment of the plain film and the normal patterns of expected air and to examine the distribution of abnormal gas pattern, divided into intraluminal and extraluminal groups. We will (a) illustrate the range of diagnoses that can be made from the plain radiograph, thus guiding further management, particularly the judicious and timely use of CT imaging, (b) discuss commonly encountered clinical problems related to abdominal radiograph imaging, and (c) describe the role of more advanced imaging techniques.

INTERPRETATION OF THE PLAIN ABDOMINAL FILM
Interpretation of plain abdominal radiograph involves an assessment of the gas, fluid, soft tissue, fat and calcific densities.1–3 This review concentrates specifically on the analysis of patterns of gas. Normal gas in the abdomen is predominantly due to swallowed air.

Air in the stomach is often seen, the pattern being somewhat variable with air fluid levels being commonly present. Small bowel air usually appears as multiple, small, randomly distributed, gaseous foci scattered throughout the abdomen. Small bowel gas is increased in patients who chronically swallow air or drink carbonated beverages. A normal small bowel gas pattern varies from no gas being visible to gas in three or four variably shaped small intestinal loops.

It is usually possible to differentiate between dilated small and large bowel on a plain abdominal radiograph. Clues include the distribution of bowel loops—the small bowel is usually located centrally and the large bowel is usually peripheral. This is referred to as ‘picture in a frame’—the small bowel being the ‘picture’ in the centre and the large bowel the ‘frame’ around the edge. The fold pattern also differentiates between small and large bowel. The small bowel folds are called valvulae conniventes, which extend across the entire lumen of the bowel loop, and the large bowel folds are hastra, which only span part way across the lumen (usually about one-third). The large bowel often has a mottled appearance in the lumen, which is representative of faecal residue.

The small bowel is dilated when its transverse diameter exceeds 25 mm in the more distal ileum and 50 mm more proximally in the jejunum. Air fluid levels in the small bowel are common but should not exceed 25 mm in length. The diameter of the colon at the caecum should not exceed 80 mm, and the remainder of the colon should not exceed a diameter of 55 mm. Air fluid levels should not be seen distal to the hepatic flexure.

TYPES OF GAS PATTERNS
Gas patterns can be broadly categorised into intraluminal or extraluminal on the basis of the anatomical location of the normal or abnormal gas within or outside the bowel (table 1).

Intraluminal
Analysis of the intraluminal gas pattern involves examining gas patterns in the lumen of the stomach, bowel and other luminal structures, such as the gallbladder, portal vein and urinary bladder, and recognising displacement of the normal bowel gas distribution due to intra-abdominal pathology.

Extraluminal
Gas seen outside the bowel lumen is abnormal, the most common site being the intraperitoneal cavity.
Certain signs are recognised on plain films, the most well cited being free gas under the diaphragm and Rigler’s sign. Free air in the retroperitoneum shows a different pattern of distribution. Gas can also be seen in the wall of a viscus (intramural air; indicative of particular pathologies), in an abscess or collection deep in the abdomen, or in the abdominal wall.

**DIAGNOSES FROM ABDOMINAL RADIOGRAPHS**

Many different diagnoses can be made from plain films. We have divided these into intraluminal and extraluminal patterns and show a number of different examples.

**Gas within the alimentary tract**

**Small bowel obstruction**

Small bowel obstruction is a common surgical problem and presents with a variable degree of abdominal pain, vomiting and abdominal distension. Plain radiography is commonly performed in the acute setting in the accident and emergency department or surgical assessment wards to look for specific evidence to support this diagnosis.

The findings on plain film are dilated loops of small bowel, measuring over 30 mm proximally and 25 mm more distally. Air fluid levels exceeding 25 mm in length are abnormal, and air fluid levels at different positions within the same loop—the ‘step ladder’ pattern—and small bubbles trapped between dilated loops—the ‘string of pearls sign’—are also indicative of small bowel obstruction. Less commonly, if the small bowel loops are dilated but completely filled with fluid, the plain x-ray will show a gasless abdomen, which should raise the suspicion of obstruction in patients in whom it is suspected clinically. The radiographic findings may be apparent 6–12 h before the clinical symptoms. Figure 1 shows some of the radiographic findings of small bowel obstruction.

Small bowel obstruction is the most common cause of intestinal obstruction and accounts for ~80% of cases. By far the most common cause in the Western world is post-surgical adhesions, accounting for ~75% of cases. In developing countries, incarcerated hernias account for the majority of cases. Other causes include gallstone ileus, foreign bodies, intussusception, intraluminal masses and malignancy (box 1).

The underlying cause of small bowel obstruction, particularly hernias, can be occasionally identified on plain films and should be looked for in cases of obstruction. It is imperative that the inguinal regions are covered on the abdominal radiograph, as these are the most common hernias to cause bowel obstruction. Obturator and umbilical hernias can sometimes be suspected from the gas pattern on plain films, with a low threshold for the prompt use of CT to elucidate further detail (figure 2). Gallstone ileus and abdominal masses causing obstruction may also occasionally be detected.

**Ileus**

A paralytic or adynamic ileus refers to stasis of the bowel contents without a mechanical obstruction. Generally more loops of bowel are involved than present in a mechanical obstruction and a diffuse pattern of dilation is present, often involving the stomach, small bowel and colon. There are a number of causes, which include postoperative states, drugs, metabolic causes and intra-abdominal inflammation. It is often

(A) Multiple loops of gas-filled distended small bowel. Note the valvulae conniventes extending across the bowel circumferentially (arrow). (B) A paucity of abdominal gas due to fluid-filled obstructed small bowel. (C) An erect abdominal radiograph showing multiple fluid levels—‘step ladder’ pattern (arrows).
Difficult to distinguish between an ileus and mechanical bowel obstruction on a plain film and CT is often used in those in whom a mechanical cause is clinically suspected. ‘Sentinel loop’ is a term used to describe a localised ileus when one loop of bowel is distended. This commonly occurs adjacent to an area of intra-abdominal inflammation, such as in pancreatitis or appendicitis.

Large bowel obstruction
Large bowel obstruction accounts for the remaining 20% of cases of intestinal obstruction. The most common cause is colorectal carcinoma. Other causes include metastatic deposits often from ovarian cancer, volvuli, diverticulitis, and rarely adhesions.

Conventional radiographs are often confirmatory in the diagnosis showing dilated loops of large bowel. The caecum distends to the greatest extent. When it reaches 80 mm, there is a high risk of perforation (figure 3). An important consideration is whether there is associated small bowel dilatation. If no gas is seen in the small bowel, this indicates that the ileocaecal valve is competent and increases the risk of associated perforation.

Sigmoid volvulus
This occurs when the sigmoid colon twists on its mesentery resulting in a closed loop obstruction. Patients may present with an acute abdomen or more insidious symptoms depending on whether the volvulus is causing partial or complete obstruction. Ischaemia is a known complication. On plain radiograph, a massively dilated loop of sigmoid colon with no haustral markings is seen arising from the pelvis and extending up to the upper abdomen quadrant usually the right upper quadrant. This has been termed the ‘coffee bean’ sign (figure 4).

Caecal volvulus
Caecal volvulus is less common than sigmoid volvulus and accounts for less than 5% of large bowel obstructions. It usually occurs in middle-aged adults, typically in those who have not undergone previous surgery. Twisting typically occurs in the ascending colon just above the ileocaecal valve. The plain radiograph is usually diagnostic and shows a marked distended loop extending from the right iliac fossa into the left upper quadrant. The small bowel is most commonly distended and the distal large bowel is collapsed. A CT scan is rarely needed to confirm the diagnosis, but will reveal the twisted mesentery and may show an ischaemic segment or perforation (figure 5).

Colitis
The features of colitis on a plain radiograph include large bowel distension, wall thickening as a result of mucosal oedema, and irregularity of the bowel wall termed ‘thumb-printing’. Toxic megacolon is the hallmark of severe colitis, which is characterised by marked colonic dilatation (figure 6). A colonic diameter of >55 mm is at risk of perforation. Acute ulcerative colitis is by far the most common cause. Others include infective, pseudomembranous and ischaemic colitis.

Gastric outlet obstruction
A massively distended stomach is the characteristic finding in gastric outlet obstruction and can be readily detected on plain films (figure 7). Gastric outlet obstruction is most commonly caused by gastric ulceration. Other causes include malignancy (involving either the stomach or pancreas), polyps, congenital lesions, volvulus or pancreatic pseudocysts. A dilated stomach may also occur in diabetic neuropathy, when no structural abnormality is present.
Gas within other luminal structures—the biliary tree and portal vein
Gas in the biliary tree (pneumobilia) is represented as a central linear branching pattern over the liver. It can be distinguished from gas in the portal vein, as this extends out to the periphery of the liver. CT will differentiate portal venous gas from biliary gas if there is diagnostic doubt. There are a number of causes of gas both in the biliary tree and the portal veins outlined below (table 2).

Previous biliary intervention
The most common cause of air in the biliary tree is an incompetent sphincter of Oddi, often seen after sphincterotomy during endoscopic retrograde cholangiopancreatography (ERCP) and is of no clinical consequence. Other forms of biliary intervention and surgery will produce the same picture.

Gallstone ileus
Gallstone ileus results in air in the biliary tree. This occurs when a large gallstone erodes though the gallbladder wall and into the small bowel. It most commonly lodges in the distal ileum, resulting in small bowel obstruction. The classic triad of radiological features on plain film are dilated small bowel, gas in the biliary tree (pneumobilia) and a calcified gallstone.

These features are only seen in about 50% of cases (figure 8). Gallstone ileus is an important cause of small bowel obstruction, which should be considered particularly in older female patients.
Necrotising enterocolitis
In neonates, portal vein gas is commonly associated with necrotising enterocolitis. This is an inflammatory condition of the small and large bowel, which predominantly affects premature neonates usually within the first weeks of life. It is a gastroenterological emergency and may result in bleeding, erosion and perforation. Evidence of gas within the bowel wall, depicted as a bubbly appearance of bowel loops, supports this diagnosis. CT in this age group is generally avoided in view of the high radiation dose.

Ischaemic bowel
In adults, portal vein gas is most commonly associated with ischaemic bowel, which has a high mortality exceeding 50% (figure 9). Other plain film findings include gas in the bowel wall as described below.

Gas in hollow viscer
Gallbladder empyema
Air in the gallbladder can result from infection. While not specifically a test used in the investigation of biliary disease, the...
plain film may show an air fluid level that is suggestive of empyema of the gallbladder. Further imaging with ultrasound or CT is usually performed (figure 10). Empyema of the gallbladder is a surgical emergency and requires urgent drainage, which is often performed via the transhepatic approach under ultrasound guidance. Other causes of air in the gallbladder include gallstone ileus and emphysematous cholecystitis, which may also cause intramural gas.

**Urinary tract gas**

Gas in the urinary bladder is most commonly seen as a result of catheterisation. It can also be seen in cases of gas-forming infection or a vesicocentric fistula, typically in association with diverticular disease. Gas can occasionally be seen extending into the ureter from the urinary bladder.

**Bowel gas displacement**

**Abdominal masses**

Although there is a broad variation of bowel gas distribution, not least due to variable fluid content in the small bowel, the displacement or atypical distribution of bowel gas may suggest soft tissue pathology in the abdomen. Bowel gas displacement is identified in the presence of organomegaly or the presence of a pathological mass within the abdomen, such as a large ovarian cyst or renal tumour (figures 11 and 12). Although plain film is not indicated to specifically look for bowel gas displacement in suspected organomegaly or malignancy, these findings may be detected when investigating other symptomatology.

**Ascites**

The presence of a large volume of ascites causes the displacement of bowel as it congregates or ‘floats’ in the central abdomen. This produces a typical pattern on plain film. This is often investigated further with ultrasound or CT, which will often determine the cause, which is often liver disease or malignancy (figure 13).

**Extraluminal gas patterns**

**Intraperitoneal perforation**

The most commonly occurring and simplest form of extraluminal gas to identify is a pneumoperitoneum. This encompasses any gas within the peritoneal cavity, typically due to a perforated gas-filled viscus. Sigmoid and duodenal perforations are the usual culprits, but other important considerations include recent surgery, post procedural, such as laparoscopy, or after controlled instrumentation, such as the use of a continuous ambulatory peritoneal dialysis catheter. Pneumoperitoneum is more easily recognised on an erect chest radiograph, hence the commonality of requesting these two radiographs in conjunction. Nevertheless, there are several well-described signs on the supine abdominal radiograph. These include air under the diaphragm, Rigler’s sign, the falciform ligament sign, triangles of gas, and the football and continuous diaphragm signs.

Air under the diaphragm is strictly speaking a chest radiograph diagnosis, with the falciform ligament and Rigler’s signs being by far the most common abdominal radiographic signs of a perforation. Rigler’s is also known as the ‘double wall sign’, as the bowel wall is crisply visualised because of gas being present on either side (within the bowel as normal) and outside the bowel (in the peritoneum). The falciform ligament sign similarly occurs, as gas on either side of it outlines an otherwise unidentified plain radiograph structure. Triangles of gas occur, as free peritoneal air is trapped between opposed bowel loops.
The rarely identified football sign gains its name from the football shaped appearance of gas outlining the peritoneum in the upper abdomen.

Retroperitoneal perforation
Much less commonly, free gas is present within the retroperitoneum. This occurs with selected perforations of the duodenum and sigmoid colon, in particular due to iatrogenic injury during ERCP. This is best identified as gas outlining either the kidney or psoas muscle (figure 16).

Intramural gas
Pneumatosi s coli and ischaemic bowel
Rarely, gas enters the wall of a viscus, such as the colon, producing an intramural gas pattern on plain films. This may be incidental and non-life threatening, such as in pneumatosis coli, or indicative of serious life-threatening pathology, as with ischaemic colitis or toxic megacolon with impending perforation. Intramural gas typically has a ‘bleb-like’ appearance due to tiny pockets of gas within the wall. This is far more sensitively detected with CT (figure 17). CT may show other associated
findings, such as bowel wall thickening or dilation, and lack of contrast enhancement in the affected segment and may also depict thrombus within the mesenteric vessels.

Gas-forming infection
Intramural gas may be present within the wall of other intraabdominal structures, such as the urinary bladder, gallbladder or aorta. Infection due to gas-forming organisms, particularly in diabetics, is the usual cause.⁴ Figure 10 shows air in the gallbladder wall in addition to air within the gallbladder itself. Figure 18 shows air within the kidney in a case of emphysematous pyelonephritis.

Superficial collections, abscesses and wound infections containing gas may similarly be evident on plain radiograph, usually depicted by a pattern of multiple different shaped gas locules. The clinical consequences of this can be serious, and prompt recognition is important (figure 19).

On occasion, usually in postoperative patients, intra-abdominal collections, such as subphrenic abscesses, can be visualised on plain radiograph. This may be either due to gas contents within the collection or displacement of normal bowel gas due to mass effect, or both (figure 20).

Common misdiagnoses and conundrums
A common misperception is that air in the rectum means that there is no bowel obstruction—the reasoning behind this being if the bowel is obstructed no air can pass through. This theory is, however, flawed, as obstruction of the bowel does not mean the
immediate disappearance of distal gas. A partial obstruction will allow the passage of air distally, and, in complete obstruction, fermentation of the residual faecal matter in the large bowel can produce gas distal to the obstruction for some time after the bowel becomes completely obstructed. Air may also be introduced during digital rectal examination, before the radiograph being performed. For these reasons, gas in the rectum does not exclude bowel obstruction, and a collapsed large bowel is generally a more reliable sign.

It can often be difficult to determine an ileus from a mechanical obstruction on a plain film. If there are also associated fluid-filled loops, these are not clearly depicted and this can make interpretation difficult. In addition, it can be difficult to determine the exact site of obstruction, particularly in the large bowel, as the loop just proximal to the obstruction can be filled with fluid and or faeces.

Perhaps the most common plain film conundrum in managing the acute abdomen is that of free intraperitoneal air under the diaphragm on chest x-ray. It can be mimicked by atelectasis at the lung bases or occasionally Chilaiditi syndrome. Chilaiditi syndrome is the result of colon or, less commonly, small bowel becoming interposed in the hepatodiaphragmatic space. The most common reasons for this are laxity of the hepatic and intestinal suspensory ligaments, redundant colon, and paralysis.

Figure 12  Bowel gas displacement II. (A) A mass (arrows) arising from the pelvis displaces bowel gas superiorly. (B) CT confirms this to be a large ovarian mass. (C,D) Massive hepatosplenomegaly (arrows) pushing the bowel gas inferiorly. This is confirmed on CT.

Figure 13  Bowel gas displacement III. (A) Plain radiograph showing centrally placed bowel loops (arrows) of normal calibre. (B) CT confirms the presence of gross ascites.
or eventration of the diaphragm. It may be possible to see the haustral folds on plain films to differentiate it from pneumoperitoneum. Being able to recognise the abdominal film findings of free air may also be of assistance in their differentiation. Further imaging with CT is often used where there is ongoing diagnostic uncertainty.

**Linking with more advanced imaging techniques**

Abdominal radiography is commonly performed in the emergency setting, as it is quick and technically easy to perform. The radiation dose is \( \sim 0.1-1.0 \text{ mSv} \) for an abdominal film. This is significantly higher than that of a standard chest x-ray (typical dose 0.02 mSv), and this should be taken into account when requesting serial examinations, particularly in young patients. The radiation dose of abdominal CT is 10–100 times greater than that of an abdominal film at \( \sim 10 \text{ mSv} \). As described in this pictorial review, abdominal radiographs may reveal abnormalities highly suggestive of specific diagnoses. They do, however, have a low diagnostic accuracy in the evaluation of abdominal pain. For example, plain radiographs only detect \( \sim 50\% \) of cases of small bowel obstruction.\(^5\)\(^6\) CT is much more sensitive and reveals the cause of small bowel obstruction in 70–90%.

**Figure 14** Signs of pneumoperitoneum I. (A) Free sub-diaphragmatic gas on chest radiograph (arrows). (B) Triangle of free peritoneal gas (arrows). (C,D) Abdominal radiograph and complementary CT scan showing the falciform ligament sign (arrows).

of cases. More recent data suggest this sensitivity is even higher and well above 90%, probably as a result of the use of multidetector CT.

CT is also much more sensitive in the diagnosis of pneumoperitoneum than conventional radiographs. Erect chest x-rays are better than abdominal films, but are insensitive to small locules of gas measuring 1 mm and only around 33% sensitive to locules measuring 1–13 mm. Another major advantage is that the site can often be identified or inferred. Clues include a concentration of extraluminal gas bubbles, thickening or inflammatory change, contrast leakage and, on occasions, a segmental defect in the bowel wall from the location of the locules of air, associated inflammatory change or contrast leakage. Generally speaking, air seen around the liver suggests an upper gastrointestinal perforation, while air seen in the pelvis, inframesocolic or supramesocolic regions suggests perforation of the colon or appendix. Accuracy of multidetector CT in determining the site of perforation is quoted to over 80%.

Plain films have also been shown to be of little value in detecting other common causes of abdominal pain such as

Figure 16  Retroperitoneal free gas. (A) Abdominal radiograph showing air outlining the left psoas muscle (arrows). (B) CT scan showing free gas (arrow) in the pelvis after rigid sigmoidoscopy causing sigmoid perforation. (C) Gas from the pelvis tracking through the retroperitoneum to lie around the left kidney (arrow).

Figure 17  Intramural gas: bowel. (A) Streaky intramural gas within the ascending colon on plain radiograph (see the magnified image); laparotomy confirmed ischaemic colitis. (B) Bleb-like intramural air on a routine barium enema study and (C) on CT in the ascending colon. This was an incidental finding and likely to represent pneumatosis coli.
appendicitis, cholecystitis, and acute pancreatitis, which are readily detected by CT in over 95% of cases and over 80% in ultrasound, with many other studies showing a similar high diagnostic accuracy of CT in the detection of the cause of acute abdominal pain. Many studies have previously shown that abdominal x-rays are requested in inappropriate settings and make little difference in patient management and are not used in accordance with the Royal College of Radiologists guidance.

Ultrasound does have a role in imaging of the acute abdomen. Accurate clinical assessment is paramount to direct the most appropriate modality of imaging. Ultrasound is excellent in the assessment of biliary disease, such as cholecystitis, renal disease and for abdominal collections. Small bowel obstruction and even free air may be detected on ultrasound often followed by further imaging with CT. One of the major benefits is the lack of ionising radiation. MRI has a long established role in the

Figure 18  Intramural gas: emphysematous pyelonephritis. (A) Speckles of gas (white arrow) in the right flank on plain radiograph along with renal large calculi (black arrow). (B,C) CT scan showing gas within the kidney due to emphysematous pyelonephritis in the context of renal stone disease.

Figure 19  Gas collections. (A,B) Multiple locules of gas within the soft tissues and abdominal cavity. (C) Extensive subcutaneous gas secondary to necrotising fasciitis. (D) CT is useful for confirming the extent of the spread to the anterior abdominal wall and retroperitoneum.
diagnosis of bile duct stones, but has also shown promising results in the diagnosis of appendicitis, particularly in pregnant women, and has been shown to be superior to CT in the diagnosis of cholecystitis. Currently, however, it has little place in the assessment of the acute abdomen in most institutions.

As a result of its unrivalled accuracy, CT in the last 10 years has revolutionised the management of the acute abdomen. In addition to answering diagnostic dilemmas, it avoids negative laparotomies and directs the surgeon to the area of pathology, so surgery can be correctly planned.

**SUMMARY**

Abdominal films have an established place in the assessment of acute abdomen despite a low sensitivity. Accurate recognition of the gas patterns depicted, however, is important for prompt diagnosis and to direct further imaging, allowing definitive management.

**MULTIPLE-CHOICE QUESTIONS (TRUE (T)/FALSE (F); ANSWERS AFTER THE REFERENCES**

**Current research questions**

1. Does the initial use of plain radiographs in the emergency setting actually change management?
2. How does site of suspected obstruction compare on plain film and CT?
3. What is the accuracy of MRI versus ultrasound in the evaluation of appendicitis?

**Key learning points**

1. Abdominal radiographs in the setting of an acute abdomen are mainly useful for suspected bowel obstruction and suspected perforation.
2. Abdominal radiographs have a much lower sensitivity than ultrasound and CT.
3. The gas patterns depicted can be divided into intraluminal and extraluminal patterns.
4. Plain abdominal radiographs may offer clues that should be examined for on every film to direct further management.

**Key references**

**Intraluminal gas**
1. Gas in the biliary tree extends to the periphery of the liver.
2. The classical features of air in the biliary tree, a calcified gallstone and small bowel obstruction are seen in approximately 80% of people with gallstone ileus.
3. Caecal volvulus usually occurs in the older population.
4. Small bowel obstruction is most commonly due to hernia in the Western world.
5. The most common cause of large bowel obstruction is a colonic tumour.

Extraluminal gas
1. Emphysematous cholecystitis typically occurs in diabetics.
2. Extraluminal gas outlines the spleen in retroperitoneal perforation.
3. Pneumatosis coli requires urgent surgical intervention.
4. Rigler’s sign is when air outlines the falciform ligament.
5. ERCP is a recognised cause of retroperitoneal perforation.
